13. ABSTRACT *(maximum 200 words)*

The implementation of *label swapping* packet-forwarding technology increases the vulnerability to insider attacks. These attacks refer to unauthorized access from within an enclave to the outside network. In this thesis we propose a protocol to counter this category of attacks. The proposed protocol provides a means for fast packet authentication. High speed is achieved by the use of a *trailer*, which allows packet filtering at Layer 2, and the use of cheap and fast message digest algorithms. To overcome the weaknesses of a 128-bit message digest algorithm, each key is designed to have a very short cryptoperiod. Such fast rekeying is implemeted by key caching (the host has a table of keys). Initial performance measurements indicated that it is possible to use our protocol while maintaining very high data throughput. Specifically, our protocol implements an authentication module, called Network Access Controller (NAC). The NAC's modular nature allows it to be easily integrated with a variety of routing technologies and other security mechanisms while remaining totally independent of them.

ABSTRACT

The implementation of *label swapping* packet-forwarding technology increases the vulnerability to insider attacks. These attacks refer to unauthorized access from within an enclave to the outside network. In this thesis we propose a protocol to counter this category of attacks. The proposed protocol provides a means for fast packet authentication. High speed is achieved by the use of a *trailer*, which allows packet filtering at Layer 2, and the use of cheap and fast message digest algorithms. To overcome the weaknesses of a 128-bit message digest algorithm, each key is designed to have a very short cryptoperiod. Such fast rekeying is implemeted by key caching (the host has a table of keys). Initial performance measurements indicated that it is possible to use our protocol while maintaining very high data throughput. Specifically, our protocol implements an authentication module, called Network Access Controller (NAC). The NAC's modular nature allows it to be easily integrated with a variety of routing technologies and other security mechanisms while remaining totally independent of them.

DISCLAIMER

The reader is cautioned that computer programs developed in this research may not have been exercised for all cases of interest. While every effort has been made, within the time available, to ensure that the programs are free of computational and logic errors, they cannot be considered validated. Any application of these programs without additional verification is at risk of the user.

I. INTRODUCTION

This thesis explores how the implementation of "Tag Switching" – a technology described in Internet RFC 2105 (Rekhter, 1997) – for Internet Protocol (IP) over Asynchronous Transfer Mode (ATM) networks can increase the risk of an *insider-attack.* We present a protocol that counters this kind of attacks using a security "gateway" termed *Network Access Controller* (NAC). We also present a prototype simulation of the protocol in C++ for demonstration purposes. Further, we evaluated the performance (in terms of overhead) of the protocol.

A. BACKROUND

1. Networking

a. Packet forwarding and "Tag Switching"

The explosive growth of the Internet has created the demand for higher bandwidth and, consequently, for faster and more effective routing and packet forwarding techniques. Specifically, today's routers are processor-based thus, computation takes place at them. In order to decide how to forward a packet they use the Network Layer (Layer-3 of the OSI model) information contained in a packet's header and in conjunction with a routing table. A good analogy of such routing in real life would be a company transporting goods (messages) by trucks (packets). Each truck has a final destination IP address and at each crossroad (router) its driver reports its destination (the packet header being parsed) and asks a traffic coordinator (routing process) for directions. The traffic coordinator has a table of destinations and the corresponding directions for leaving the crossroad (routing table). He looks up the table and directs the driver to the right road (routing decision).

The routing table at a router must be updated periodically to reflect topological changes or road fluctuations in the network. Each packet's header has to be parsed by the routing process. All these functions are currently implemented by specialized software. In summary, Layer-3 processing is complex, computationally costly

(time consuming) and the equipment required is expensive. Nevertheless, it has been the choice because it is very flexible and very functional as shown by Internet's exponential growth.

Switching, on the other hand, is faster and less complex than routing, and the equipment (switches) are cheaper. It has been reported that for the same throughput, routing costs 20 times as much as switching (Newman, 1998). Switches use the Data-Link Layer (Layer-2 of the OSI model) information contained in a packet's header in order to forward the packet to its destination according to fixed rules. This functionality is implemented, usually, in hardware. An analogy of switching with the real world can be found again using the transportation company paradigm. A racecar leaves the company's headquarters and finds the best way to the destination (signalling). The racecar carries a paintbrush that paints the road with a fluorescent color. The truck drivers now need not know their destination; they only have to follow the paint. The only problem with Layer-2 switching is that it is not as flexible and functional as Network Layer routing because any change in the route would require repainting the entire road from the beginning.

Recently a number of new technologies have emerged that combine the Layer-2 switching with the Layer-3 routing for performance, flexibility and functionality. They include Cisco's *Tag Switching* (Rekhter, 1997), Ipsilon's *IP switching* (Newman, 1998) and 3Com's *Fast IP* (Seaman, 1997). Although there is not yet a standard, all of these technologies follow the so-called *label-swapping* paradigm for packet forwarding. This paradigm can be described simply as follows: A *label* or "tag" (i.e., an integer) is assigned to a packet[1] according to the *flow*[2] to which it belongs. Packet forwarding is based solely on this label. The implementation of Tag Switching and Fast IP is independent of the lower network layers[3] (Layers 1 and 2 of the OSI model). Therefore, they are flexible and adaptable.

---

[1] The label is carried by the packet as part of its header.

[2] A sequence of packets with common attributes e.g., those carrying data for a video stream or a multimedia file.

[3] Only *IP switching* is closely coupled with ATM.

b. Asynchronous Transfer Mode

The Asynchronous Transfer Mode (ATM) protocol is a connection-oriented protocol for computer communication, analogous to the telephony. It is designed to carry data at extremely high speeds (e.g., 622Mb/s). ATM uses fixed size (53 byte) packets called *cells* (Figure 1), which travel in virtual channel connections (VCCs), established between senders and receivers. In ATM, the cells that travel in one VCC constitute a *flow*. The setup and teardown of a VCC are performed by *signalling* functions. The term *virtual* is used because a single physical medium (e.g., fiber optic) can be utilized to accommodate the traffic of many Virtual Channels (VCs). Once a VCC has been established, the switching of the cells inside an ATM switch is done in hardware.

The *Virtual Channel Identifier* (VCI), an integer stored in each cell's four-byte header is used by switches to forward cells to the right VCs. Each cell's incoming VCI will be translated into a new one (the outgoing VCI) inside each switch. Each switch maintains a table that maps the incoming VCIs to entries containing two elements: a new VCI and the appropriate output port. These tables are updated during the *connection setup*[1] phase. It is obvious that ATM switching follows the *label swapping* forwarding paradigm.

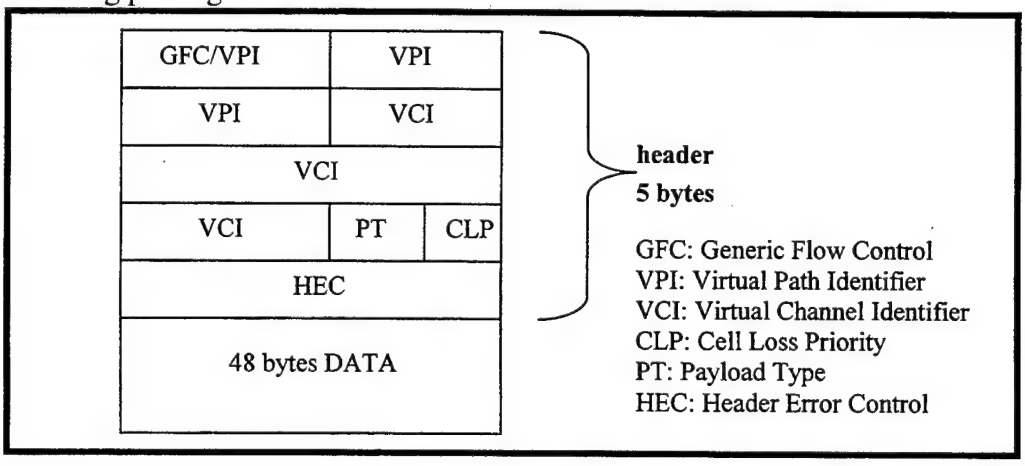

Figure 1. ATM cell format

[1] A *signalling* function. Signalling functions are responsible for setting up, maintaining and tearing down a connection and use *permanent* or *semi-permanent* VCs dedicated to signalling.

Another attractive feature of ATM is that the users can request quality of service (QoS) for a VCC. Four *ATM service classes* provide different levels of QoS. They are:

- *Constant Bit Rate* (CBR): guaranteed transmission rate for applications that need it, e.g., 12 Mb/s for a videoconferencing VC.
- *Variable Bit Rate* (VBR) (*real-time* and *non-real-time* versions): a *standard* transmission rate (SCR) is assigned to a connection. This rate can momentarily rise to the *peak* transmission rate (PCR) in order to accommodate the needs in bandwidth of bursty transmissions. Real time (RT) version is required when an application needs to maintain a timing relationship between two users e.g., in voice applications. Non-Real Time (NRT) can be used when information retrieval at a later time will not cause any problem e.g., store and forward video.
- Available Bit Rate (ABR): low *cell loss*[1] but the available bit rate fluctuates, depending on the network resource availability.
- Unspecified Bit Rate (UBR): these cells are the first ones lost when congestion occurs.

Although ATM is being heavily promoted, especially by the telecommunications community, its deployment has been slow mainly because of the existence and success of the IP. It is clear today that the ATM technology will not totally replace IP. However, the advantages of ATM – high speed and QoS – led to the development of techniques that combine IP and ATM. These are the Classical IP over ATM described in RFC 1577 (Laubach, 1994) and the LAN emulation (LANE)(AF-LANE 0084.000, 1997).

[1] Cell loss can happen when *congestion* occurs, e.g., when cells arrive at a switch at higher rates than the ones that the switch can forward them, this results in *buffer overflow* and consequently in cell loss.

2. Network Security

The Internet is often called "the network of networks". Interconnectivity at this scale has created the need to protect an organization's network against malicious or accidental behaviors. The same argument holds for a subnet connected to a corporate intranet and for a site connected to a subnet. In order to safeguard a network or a network segment, a security policy must be set for the network. After setting the policy, the administrator(s) must choose tools that help enforce the security policy. These tools include boundary controllers, encryption (and hashing) algorithms, access control and authentication mechanisms.

A firewall isolates an internal network segment from the outside world and allows access only to authorized traffic (Figure 2). Additionally, it controls access from the internal network to the Internet (or an intranet).

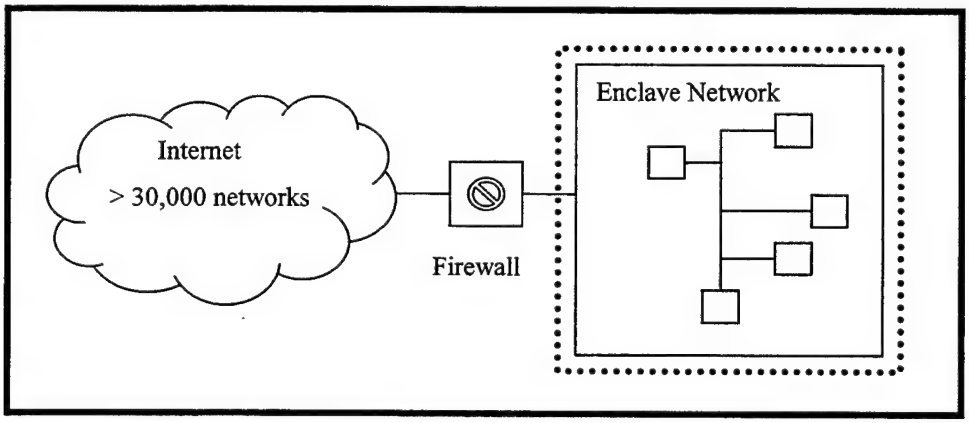

Figure 2. A firewall protecting an enclave. After (Hare, 1996).

Below are two examples from (Hare, 1996) that demonstrate this functionality. They are implemented in the freely available firewall program *TCP Wrapper*.

- Example 1: the entry in the*/etc/hosts.allow* file:

  fingerd, telnetd: 144.19.74.1, 144.20

  allows host 144.19.74.1 and all hosts on class B network 144.20.0.0 to access *telnet* and *finger* services.

- Example 2: the entry in the */etc/hosts.deny* file:

Fingerd, telnetd : .hacker.org

denies access to *telnet* and *finger* services to all hosts in the domain HACKER.ORG.

Encryption algorithms can be used as parts of protocols that can support *confidentiality*, *integrity*, *authentication*, *non-repudiation* of information travelling between computers. There are many of them. Two widely used ones (Schneier, 1996) are:

- DES (Data Encryption Standard) is the most popular. It uses the same key for encryption and decryption (*symmetric* algorithm). The common key is *secret.* The algorithm transforms data into an unmeaningful series of bits. If the key becomes available to an attacker then the algorithm is compromised (broken).
- RSA (named after its creators – Rivest, Shamir and Adleman) is the most popular *public key* algorithm. The only *secret* key is the private key, which is known only to its owner. The *public* key is available to others. Data encrypted by a user's private key can be decrypted only by the same user's public key and data encrypted by a user's public key can be decrypted only by the same user's private key.

Message digest[1] algorithms can be used to provide message authentication and data *integrity*. The whole message is *mapped* by the keyed one-way hashing function to a (usually) small *hash value* or *message digest* or *message authentication code (MAC).* This value serves the role of the *signature* for the particular message. The most widely known message digest algorithms are the ones of the MD family (MD4 (Rivest, 1990), MD5 (Rivest, 1992)) written by Ron Rivest (RSA) and the Secure Hash Algorithm (SHA). The SHA is part of Digital Signature Standard (DSS)(NIST, 1994) which is a protocol used for creating *digital signatures*.

[1] Known also as *keyed one-way hash functions.*

Finally, the *authentication and key-exchange mechanisms,* usually implemented by centralized authentication servers, allow access to resources only to authorized users. Two popular authentication services are:

- *Kerberos* which uses conventional encryption and
- *X.509-based key exchange*, which is part of the Privacy Enhanced Mail (PEM) protocol and uses public key encryption (RSA is recommended as its underlying public key encryption algorithm).

A more detailed discussion around Network Security follows in Chapter II of this thesis.

B. SCOPE OF THE THESIS

This thesis examines the vulnerabilities introduced to a network by the implementation of Tag Switching. In particular we have focused on security problems related to unauthorized access from the internal network (*enclave*) to the outside world. We call them *insider attacks*.

Specifically we propose a protocol that will guard against this category of attacks and we evaluate the performance of the protocol. Further, a prototype simulation of the protocol in C++ is presented.

C. ORGANIZATION

The thesis is organized as follows: Chapter II gives an overview of *network security* issues related to firewalls and message authentication. Chapter III *discusses high speed networking* issues, in particular IP over ATM and Tag Switching. Chapter IV presents *insider attacks* (the problem) and our *protocol* (the proposed solution), including our assumptions. Chapter V presents the performance evaluation of the protocol. Chapter VI presents the conclusions we reached and describes future work that could follow this thesis.

Note that in Chapters II and III, we focus on the aspects of network security and high-speed networking that are related to the thesis. Both chapters are presented for background information. The simulation source code and the software engineering notes about the code are included as Appendixes. We have also included as an Appendix the measuring code that was used for the performance evaluation of the protocol.

D. MAJOR CONTRIBUTIONS OF THIS THESIS

There are three major contributions of this thesis.

- It examines the vulnerabilities of newly proposed packet forwarding technologies that use the *label-swapping paradigm* – in particular Tag Switching.
- It proposes a flexible[1] solution (protocol) that can be implemented in a straightforward manner.
- It provides an initial evaluation of how the implementation of the protocol affects the performance of Tag Switching when it is used for IP over ATM.

[1] Can be adapted to any label swapping technology.

II. NETWORK SECURITY

A. SCREENING ROUTERS AND FIREWALLS

A fundamental measure for home security is locking the door. However, one must be able to examine each person that knocks on the door and allow him/her to enter when it is desired. The same action should take place at the perimeter of a network segment (site, enclave or intranet). In the network case, arriving packets are checked (and not persons). These packets may arrive from the rest of the network, intranet and finally from the Internet. Additionally we want to control the access from inside the enclave to the outside world. Such functionality is known as *access control*, and it is implemented by devices generally known as *firewalls*. The use of firewalls is a common practice today.

A Discretionary Control Mechanism (DAC) may be in force as part of the security policy of an enclave. In the context of such a mechanism, the security officer of the enclave may decide to prohibit a user access to the outside world. For example, the ISSO may have granted Bob access privilege to the outside world, but has not done so with Alice. In this case, the packets that Alice is sending must be *denied access* to the external network.

A definition of a *firewall* is "a collection of components that are placed between two networks that create controlled isolation" (Cheswick, 1994). It may be inappropriate to use the term *firewall* for a variety of products and architectures. Nonetheless, it is now a general term in the literature. "Firewall" also has become a synonym for *Internet Firewall*, because it has been common for firewalls to be used as isolating devices between corporate or other types of networks and the Internet. In fact, firewalls can exist between any two networks.

The existence of a firewall increases the security of a network because by using a firewall one can enforce aspects of the network's security policy. When and how access to a resource (host, network or service) is allowed depends, and directly reflects, this security policy. Detailed information on network security policy can be found in chapter 3 of (Hare, 1996). We must emphasize here that firewalls control the access to resources

in *both* directions: from the outside world into the network and from the network to the outside world.

The following three main techniques are used in firewalls[1]:

- *Packet filtering* occurs when the firewall decides to forward or to block a packet based on some rules. The packet header is parsed and according to the type of the protocol and/or the values in the fields of the packet header e.g., the source or destination address, the packet is allowed to proceed or not. The firewall therefore can control the type of network traffic and the type of services available in a network segment. The term *screening routers* or *packet filter routers* are used for the devices[2] that perform this screening task. Since each set of fields in the packet header is added to the packet by a layer of the OSI Reference Model, we can identify exactly at which level the filtering functions takes place. Usually screening routers perform their screening functions at the network (a.k.a. Layer 3) and the transport layers (a.k.a. Layer 4) of the OSI Reference Model. Sometimes, however, filtering can happen at the data link (a.k.a. Layer 2) or even at the physical (a.k.a. Layer 1) layers. (Hare, 1996)

- *Circuit gateways* are used to establish, for authorized users, a channel of communication between two network segments (networks, subnets, sites). The main concern is *who* is using an application and not what information is passed by the network application. Circuit gateways are similar to packet filters. Additionally they use the services of an out-of-bound authentication scheme that provides the information needed for authenticating a user.(Atkins, 1997)

- *Application proxies* are used when it is important to control the content of the data to an application. An example of such a proxy is one used to limit FTP

[1] Details for all of the techniques can be found in (Atkins, 1997).

[2] They are commercial routers that are capable of screening packets.

users so that they can only get files from the Internet, but never push local files to the Internet. The problem with application proxies is that they are application specific and therefore, difficult to write and maintain. Application proxies can be combined together with circuit gateways in firewall products. (Atkins, 1997)

We are interested in combining the packet filtering and circuit gateways techniques in our design of the NAC.

B. MESSAGE AUTHENTICATION FUNCTIONS

Computer networks are vulnerable to a number of attacks. We describe some of these attacks in order to give a perspective of the potential threats to a network. Message authentication is one of the effective measures against a broad spectrum of network attacks. We describe three classes of message authentication in this section.

1. Network Attacks

Stallings describes the possible attacks in computer networks (Stallings, 1995):

- *Disclosure*: the contents of a message become available to an unauthorized to know person or process
- *Traffic analysis*: a pattern of traffic between the communicating entities is identified. Information such as frequency and duration of connections[1], number and size of messages can be deduced.
- *Masquerade*: an malicious source creates and inserts messages into the network. These messages may be purported to come from an authorized entity, they may be faulty acknowledgements of messages etc.
- *Content modification*: the contents of a message are changed, deleted or modified.

[1] In connection oriented communications such as ATM.

- *Sequence modification*: the sequence of messages is altered. New messages may be inserted, messages can be deleted or simply reordered.
- *Timing modification*: Messages may be delayed or replayed. An individual message (e.g., datagram), an entire session or a sequence of messages belonging to a previous, valid session can be replayed or delayed.
- *Repudiation*: a source denies that it ever sent a message or a destination denies that it ever received a message.

2. Authentication Functions

Message authentication can counter masquerade, content modification, sequence modification and timing modification. Repudiation is specifically countered *by digital signatures*. (Stallings, 1995)

Message authentication mechanisms consist of two parts:

- *Authentication function*: produces an *authenticator* (a value that authenticates the message) known also as *Message Authentication Code* (MAC).
- *Authentication protocol*: the sequence of actions that verifies the authenticity of the message. (Stallings, 1995)

The first part of a message authentication mechanism, the authentication function, can be further classified in the following three classes:

a. Message encryption

The ciphertext of the whole message is used as its authenticator. There are two different ways to authenticate a message: using a conventional (symmetric) encryption method and using a public-key encryption method.

When a conventional encryption scheme is going to be used, if a message M has to be exchanged between two parties S (source) and D (destination) and the shared secret key is K, then the following scenario takes place:

- S encrypts M using K and produces the encrypted message: $E_K(M)$.

- S sends E_K (M) to D.
- D decrypts E_K (M) using K and gets message M: $D_K (E_K (M)) = M$.

If the key is known only to S and D, then D can be confident that message M came from S. However, the degree of authentication is limited. The key K could have been compromised or the encrypted message could have been a *replay*. Additionally when D is an automated system, and not an intelligent person, and message M is a stream of bits, it is very difficult for D to judge for M if it is an acceptable stream of bits or not. A video or an audio stream falls into this category. Any alteration could not be detected by an automated system. The result of this weakness of automated systems in the previous example would be that D, falsely, may assume that any E_K (M) has come from S. Therefore, additional formatting of the method and additional redundancy is needed for using it in automated systems. (Stallings, 1995)

In a public-key encryption scheme if the message M is encrypted with the public key of D, denoted KpuD, no authentication can be provided. The obvious reason is that any one that knows KPuD (since it is public, and therefore, available to every one) could have send the message E_{KPuD} (M) to D. Authentication can only be provided when the sender S uses his private key, denoted KPrS, to encrypt M. The result is E_{KPrS} (M) and it can be decrypted by anyone that has S's public key KPuS. This may affect the confidentiality of message M but D now can be certain that S is the sender of M.

We can eliminate the disadvantages and get only the benefits from the two public-key encryption scenarios that we mentioned if we use – paying the additional cost in performance and complexity – the following, *double* public-key encryption, scenario:

- S encrypts M using KPrS and produces the encrypted message:

  $E_{KPrS}(M)$.
- S encrypts E_{KPrS} (M) using KPuD and produces the encrypted message: E_{KPuD} (E_{KPrS} (M)).
- S sends $E_{KPuD}(E_{KPrS}(M))$ to D.

- D decrypts $E_{KPuD}(E_{KPrS}(M))$ using KPrD and gets message $E_{KPrS}(M)$: $D_{KPrD}(E_{KPuD}(E_{KPrS}(M))) = E_{KPrS}(M)$. (this step provides *confidentiality*).

- D decrypts $E_{KPrS}(M)$ using KPuS and gets message M: $D_{KPuS}(E_{KPrS}(M)) = M$. (this step provides *authentication*).

It is obvious that similar problems exist here, as with the shared key encryption scheme. Again, it is difficult for an automated D to reject a series of bits M as unmeaningful and replays can take place as well as it was possible in the conventional encryption scheme. Therefore, some refinement of the method is needed here, as well as in the conventional encryption scheme, in order to use it as an authentication scheme.

b. Cryptographic checksum

The sender S (source) and receiver D (destination) must share a secret key K (similarly to a conventional encryption scheme). S applies an *encryption-like* algorithm to the message M using the common key K. This algorithm produces a small, fixed length set of bits known as a *cryptographic checksum* or *message authentication code* (MAC). The MAC is then appended to the message M and both are sent to D. D recalculates the MAC (applying the same algorithm) for the received message, using its copy of the key K. The message is authenticated if the received MAC and the calculated MAC are the same. D can also be certain that M has not been modified (otherwise, the calculated MAC would not be the same with the MAC received). The obvious vulnerability of the method is when the secret key K has been compromised.

The method does not provide confidentiality. In the case that the communicating parties need confidentiality, as well as authentication, the message should be encrypted (it is recommended that MAC is calculated for the plain text M and not after the encryption (Stallings, 1995)).

The difference between the algorithm that is used for the MAC calculation and that of a conventional encryption function is that the former does not need to be reversible (it is a one-way encryption function) as it must be for decryption. This makes it

harder to break than encryption. Additionally the result is a compact representation of the message. (Stallings, 1995)

(Davies, 1989) suggests the use of MAC in the following three cases:

- Authenticating control messages in a network. Each control messages is broadcast with its MAC. A network node, playing the role of the *authentication monitor,* that has the secret key, authenticates the message or alerts all the recipients that the message is fake.
- When a heavy load of incoming messages floods the receiver D. We cannot afford the resources to decrypt all of them. An authentication scheme that performs selective MAC checking on a random basis can be used.
- For executable programs, an attached MAC could be used for assuring their integrity.

(Stallings, 1995) adds three more rationales to the above:

- When secrecy is not required but it is still important for messages to be authenticated. An example is the Simple Network Management Protocol version 2 (SNMPv2). In SNMPv2, the functions of confidentiality and authentication are separated. The incoming messages may not need to be secret, nevertheless, they have to be authenticated, especially when they change parameters at the managed system.
- Separation of confidentiality and authentication functions allows for flexibility in the architecture. The designer may choose in which layer of the OSI model to apply the one or the other. A possible decision could be to apply authentication (MAC) at the application layer (Layer 7) and confidentiality (using encryption) at the transport layer (Layer 4).
- When we want to protect the integrity of the contents of a message after it is decrypted. A MAC for that message can ensure that its contents have not been fraudulently modified.

c. *One-way Hash Functions*

This is a variation of the previous method. A public function, *H*, is used to map each message *M*, regardless of its length, into a *hash value* or *hash code h,* of fixed length *m*

$$h = H(M), \text{ where } h \text{ is of length } m$$

The whole point of the one way hash function is to provide a "fingerprint" of M that is *unique* (Schneier, 1996). The hash code is a function of every bit of the message. This provides an error detection capability since a change in only one bit of the message would result in a change the hash value (Stallings, 1995).

The characteristics of hash functions that make them *one-way* are (Merkle, 1979):

- Given *M*, it is easy to compute *H.*
- Given *H*, it is hard to compute *M* such that *H(M) = h.*
- Given *M*, it is hard to find another message, *M'*, such that *H(M) = H(M').* (collision resistance[1])

A *keyed* variation of one-way hash functions a.k.a. *messages digest* functions can be used for message authentication. The actual ideas for the usage of keyed hash function are old, some of the proposed methods[2] *append*[3] (Tsudik, 1992) (Galvin, 1991) or *prepend*[4] (Galvin, 1991) or even do both (*envelope method*), a secret key (or *two*) to the message before the one-way hash function is applied. The benefit of using message digest functions instead of the previous two methods of authentication, given the hypothesis that confidentiality is not required, is that they are less computationally intensive than encryption, therefore, they are faster. Additionally there are several other

---

[1] Collision resistance is a very important property of hash-function however it is beyond the scope of this thesis to discuss issues related to that (strong, weak, etc.).

[2] Appearing in SNMPv2.

[3] Secret Suffix Method.

[4] Secret Prefix Method.

reasons indicating that encryption should be avoided – even when it is available in hardware implementation – whenever possible. (Tsudik, 1992) points out them:

- Encryption software is slow, even for a small amount of data.
- Encryption hardware is not extremely expensive but the cost adds up as each node in the network must be equipped with this hardware.
- The overhead to initialize encryption hardware for small blocks of data is very high, mainly because encryption hardware is usually optimized for large data blocks.
- Encryption algorithms are subjected to U.S. export control.
- Some of the algorithms are patented, like the RSA public-key algorithm, and there is an additional cost for licensing them.

Two of the most popular – and fast – one-way hash functions are the MD4 (Rivest, 1990) and its improvement, the MD5 (Rivest, 1992). Both were designed by Ron Rivest, and they produce a 128-bit message digest of the input message. Another famous algorithm is SHA (Secure Hash Function). It was introduced by NIS, along with NSA for use in DSS (Digital Signature Standard)(NIST, 1994). It produces a 160-bits but it is based on principles similar to the MD algorithms. According to (Schneier, 1996) there are no known cryptographic attacks against SHA and because it produces a 160-bit hash value it is more resistant to brute-force attacks than 128-bit hash functions.

An interesting variation of *keyed* hash functions is proposed in (Preneel, 1995). The authors first expose the vulnerabilities of previous proposals of keyed hash functions and then they propose to include a key at the beginning, at the end and in every iteration of the algorithm in order to strengthen it. The new algorithm is called MDx-MAC and the authors claim for the proposed method that:

- It maintains the benefits of keyed one-way hash function usage (minimum implementation effort – maximum confidence).
- The performance would be close to that of a one-way hash function.

- The required resources (memory etc.) for its implementation would be similar to that of a one-way hash function.
- It is generic (can be used with any algorithm with the same principles as MD4).

C. SUMMARY

In this chapter, we discussed computer security issues that are of interest as a background for this thesis. We are interested in particular in two categories of firewalls: *packet filtering firewalls* and *circuit gateways*, and in message authentication using *keyed hash functions*. The next chapter discusses networking issues of interest.

III. HIGH SPEED NETWORKS

A. IP OVER ATM

ATM has been chosen by International Telecommunication Union (ITU-T Recommendation I.121) as the basis for the Broadband Integrated Services Digital Network (B-ISDN). An *Integrated Services* network is one that can be used to carry all types of traffic: data, voice, video etc. "Broadband" means simply *high link speed* (up to Gigabits per second)[1]. ATM networks are being installed in both research[2]and commercial environments[3].

The Internet Protocol (IP) is the foundation protocol for the most widely used packet-switched network, the Internet. The popularity of IP is ever growing with the growth of the Internet.

It is becoming increasingly important to interconnect IP and ATM networks. The easiest way to do so is for IP to treat ATM as a link-level (Layer-2 of the OSI model) technology (like Ethernet or FDDI), ignoring the routing and quality-of-service aspects of ATM. This approach is called *IP over ATM* (Figure 3), and it is still an area of active research. Additionally there is not a universally accepted method for IP over ATM. (Keshav, 1997)

It is beyond the scope of this thesis to examine in depth the different proposals of implementing IP over ATM. However, we think it would be useful, as background, to briefly describe the following:

- The method of IP encapsulation in ATM Adaptation Layer 5(AAL5),
- Cell loss detection Classical IP over ATM (CIP), and

---

[1] The term comes from the cable television: *baseband* is a single signal used for video, the band of frequencies can be chosen from the base of the spectrum; when many of these signals are modulated and fed into a cable a *broad band* of frequencies are used for all the channels(Kercheval, 1998)

[2] University of Southern California – Advanced Biotechnical Consortium (USC-ABC).

[3] Texaco, McDonalds, Chrysler.

- LAN Emulation (LANE).

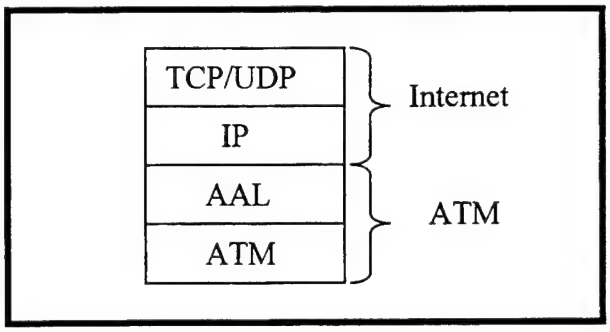

Figure 3. IP over ATM model.

1. IP encapsulation in AAL5

The ATM Adaptation Layer lies on top of the ATM layer Figure 4. AAL adds functionality to the ATM layer, making it more suitable for higher layer protocols or applications. AAL corresponds to the network layer (Layer-3) of the OSI model[1] (Figure 4). Five different AAL versions were developed in order to accommodate the diversity of existing applications. AAL5 is the latest version and possibly, the only one that will be used by future ATM networks. AAL5 provides:

- A mapping of the high-layer data into a cell-stream.
- Cell loss detection.

The higher-layer data are grouped into packets that may have a maximum size of 64 Kbytes. These packets are called *frames.* The AAL5 functionality is achieved in three sublayers:

- The Segmentation and Reassembly (SAR) sublayer distributes the higher-layer data into cells at the sender and reassembles the data at the receiver. It lies directly on top of the ATM layer.

---

[1] There are arguments that AAL is a datalink layer (Layer-2) however, AAL is a network layer because it provides end-to-end connectivity (even though it does not provide addressing and routing) and it provides a view to the transport layer (Layer-4 of the OSI model) similar to that of a transport layer over IP (Keshav, 1997).

- The Service Specific Convergence Sublayer (SSCS) which lies below the higher-layers. The SSCS is a "shim" layer that fits the upper layer protocols to the AAL. Different applications from higher-layers (e.g., IP, TCP, UDP) send/receive their Protocol Data Units (PDUs) (a.k.a. packets), which "converge" at SSCS.
- The Common Part Convergence Sublayer (CPCS) is the middle layer of the AAL (between SAR and SSCS). The CPCS performs functions common to all protocols.

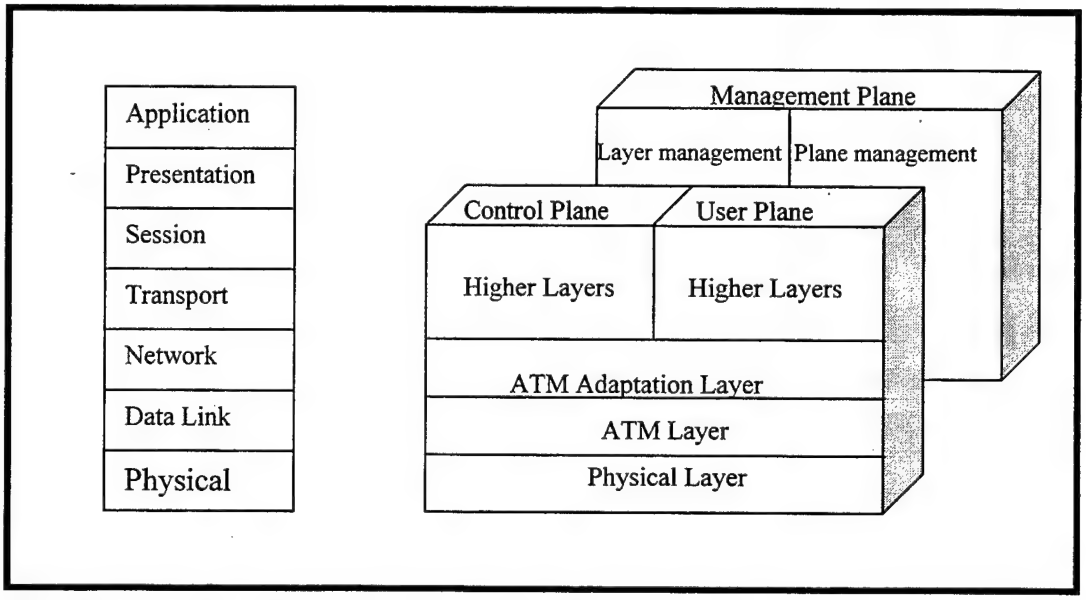

Figure 4. The OSI Model and the ATM Protocol Model. After (Kercheval, 1998)

Below we discuss the two steps required for IP over ATM using the AAL5:

- *Encapsulation of IP datagrams in AAL5 frames*: each IP datagram is put in the data field of an AAL5 frame. The IETF requires an additional *encapsulation layer* to add an 8-byte header to identify which protocol uses the frame. This layer is interposed between the IP layer and the AAL5 layer.(Keshav, 1997)
- *Translation of the IP destination address to an ATM destination address.* There are two major approaches: *classical IP over ATM* and *LAN emulation.* They are described in the next two subsections.

2. Classical IP over ATM

IP (Ipv4) uses 4-byte addresses. ATM uses variable length Network Service Access Point (NSAP) addresses. A protocol similar to Address Resolution Protocol (ARP)[1] could be used for translating an IP address to an ATM one. A problem is that ARP assumes that the LAN supports broadcast, whereas an ATM LAN does not[2]. A solution would be to have an ATM host to play the *ARP server* role. The ARP server translates IP addresses to ATM addresses using a table that contains addresses mappings (from IP to ATM and vice versa) for all the LAN members. When an ATM host wants to send an IP packet to another host in the same LAN, it queries to the ARP server sending its own ATM address and the IP address it wants resolved. The ARP replies with a message containing the address translation. (Keshav, 1997)

The above scheme, when applied to very large ATM networks with thousands of IP/ATM hosts, would create a lot of overhead traffic every time a broadcast (which is common for Internet Protocols) was sent. The classical IP over ATM model partitions the larger ATM network into a set of IP subnets called *logical IP subnets,* or *LISs*, to reduce this traffic. A broadcast from a host can only reach the other hosts on the same LIS. This solution, however, introduces the following problem. A host has no way of knowing if there is a direct ATM path to a host in another LIS. Therefore, in the case where a host in another LIS has to be contacted, the sender must first set up a VC to an IP router. The router accepts the packet and uses IP routing to decide its destination. If the packet is destined to another LIS in the same ATM network, the router opens a VC to the destination (host or another router) and forwards the packet. If the packet destination is not reachable using ATM, the packet is forwarded using normal IP routing. (Keshav, 1997)

The problem with the previous approach is that even if a direct ATM path exists between two hosts, if the hosts belong to different LISs then they are obliged to go

---

[1] ARP is used to translate IP addresses to datalink Medium Access Control (MAC) addresses.

[2] An ATM LAN is a *nonbroadcast multiple access (NBMA)* LAN.(Keshav, 1997)

through a router every time they wish to establish contact with each other. Katz proposed the *Next Hop Resolution Protocol* in order to address this problem (Katz, 1996). A *Next Hop Server (NHS)* stores IP to ATM address translations for all the hosts (that have registered with it) in the ATM network. The registered hosts are considered part of a logical group called *nonbroadcast multiple access (NBMA) subnetwork* (similar to a LIS). If the IP address can be resolved by the NH server, the destination is contacted over an all ATM path, and IP routing is bypassed (this method of routing is called *cut-through* routing). Otherwise, the packet is forwarded to the local IP router for transmission (as it was done before). (Keshav, 1997)

An additional problem that IP over ATM must address is the translation of multicast IP addresses (a.k.a. Class D addresses). The problem is caused by the fact that ATM is a nonbroadcast technology. A Class D address must be translated to a set of ATM addresses. The process must be dynamic to accommodate changes to the multicast group. The problem can be solved by having an ATM switch create *point-to-multipoint* connections[1]. Two such techniques have been developed:

- The Class D address is associated with a *multicast server* that coordinates the multicast. The server maintains single connections with all the receivers (point-to-multipoint connection). The sender(s) send packets to the server. The server sends the packets to the receivers.
- Each sender maintains a separate point-to-multipoint connection to every receiver in the group. The multicast connection is therefore achieved by a set of point-to-multipoint connections.

In both techniques the translation of a Class D address to a set of ATM addresses is provided by a *multicast address resolution server (MARS)* (Armitage, 1995b). A MARS is an extension of an ARP server with the additional capability to maintain a point-to-multipoint connection – called *cluster control VC* – to every ATM destination in the LIS. The cluster control VC is used to update the mapping from a Class D address to

[1] A virtual circuit that sends cells from a single source to multiple destinations.

a set of ATM addresses as receivers join and leave the multicast group. More details can be found in (Armitage, 1995a).

3. LAN Emulation (LANE)

Continuing with our background information discussion, we will discuss LANE. LAN emulation is the ATM Forum's attempt to make ATM interoperate with the so-called "legacy" networks that include Ethernet and Token Ring (even FDDI). The emulated LAN, however, must be one or the other. A router must be deployed if we want to communication between two emulated LANs. (Kercheval, 1998)

As we have discussed in the previous section, IP over ATM allows IP traffic to be sent to any destination on the ATM LAN or elsewhere simply by translating IP addresses to ATM ones using an ARP server. Classical IP over ATM restricted the destination to be in the same LAN (either a host or a router). It is obvious that if this is the case, the address translation can be done under the data link layer (Layer-2 of the OSI model). The advantage of translating an address under the data link layer is that the address translation is not IP specific. In this case the address translation scheme can be used to carry protocols other than IP over ATM. (Keshav, 1997)

Alternatively, address translation can be achieved by inserting an extra layer, called *LAN emulation client (LEC),* between the data link (MAC) layer and the AAL5 (Truong, 1995). When the LEC layer receives a packet carrying a MAC address, it first checks to see if the MAC address is unicast or multicast. If it is multicast, the packet is sent to a *broadcast server*, which sends a copy of the packet to every host on the LAN. (LANE v2 (AF-LANE, 1997) supports *enhanced multicast,* a form of multicast where not all hosts must receive multicast traffic.) If it is unicast, the ARP cache is checked to see if it already has a translation from the MAC address to an existing VC. If no VC exists, the LEC sends an ARP message to a *LAN emulation server (LES),* requesting resolution of the address. (The LES stores the translation of every MAC address in the LAN.) The ARP responds to the LEC with an ATM address and the LEC uses it to set up a VC. (The LANE endpoint must be capable of ATM signalling (Keshav, 1997).)

Since LEC and LES operate at the data link layer, any network layer protocol can use LANE without modification. ATM, therefore, can replace Ethernet or Token Ring in a straightforward manner (Keshav, 1997). In LANE v2, LECs can request for a particular class of quality of service (QoS)[1] when they set up the VC[2]. That was not possible in v1 where all traffic was treated as belonging in the Unspecified Bit Rate (UBR) class. Detailed information about LANE can be found in (AF-LANE, 1997).

B. TAG SWITCHING

The following is a summary of (Rekhter, 1997), which contains an overview of Cisco Systems' Tag Switching architecture. Tag Switching is a novel approach to Layer-3 (network layer) packet forwarding. The claimed features of the Tag Switching technology are the following:

- The use of the simple *label swapping* forwarding paradigm improves the forwarding performance.
- A tag[3] can be associated with a wide range of forwarding granularities so the same forwarding paradigm can be used to support a variety of routing functions. For example, in one case a tag can be used for destination-based routing (the tag is associated with a point-to-point connection), while in another case a tag can be used for multicast (the tag is associated with a point-to-multipoint connection).
- The simplicity of the forwarding paradigm, the wide range of flow aggregation granularities and the fact that the forwarding paradigm remains the same enables a tag switching system to gracefully evolve to accommodate emerging requirements.

---

[1] You can have Available Bit Rate (ABR).

[2] A signalling function.

[3] A tag is defining a flow.

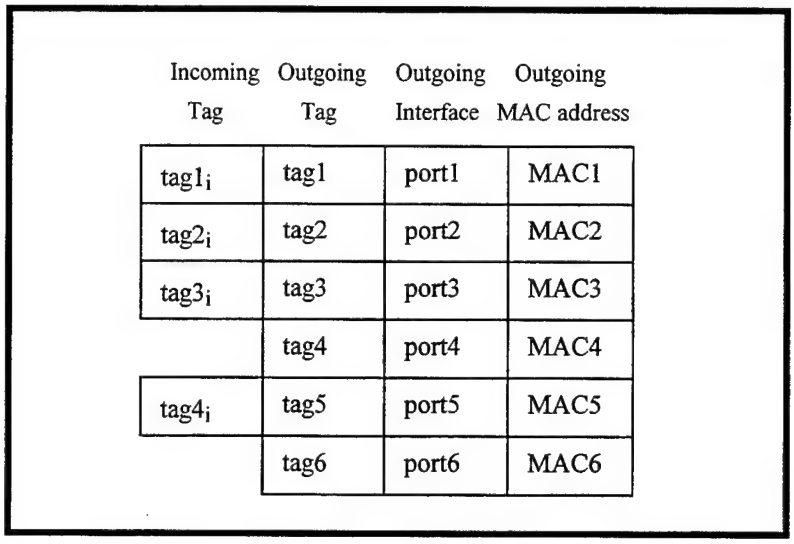
Next, we describe the two main components of Tag Switching architecture: the *forwarding* component and the *control* component.

1. Forwarding Component

When a packet with a tag is received by a tag switch, the switch uses the tag as an index in its *Tag Information Base (TIB)* (Figure 4). The TIB contains entries that consist of an incoming tag, and one or more sub-entries[1] of the form [*outgoing tag, outgoing interface, outgoing link level information*]. The switch looks in the TIB to find an entry that has an incoming tag equal to the tag carried in the packet. If the tag is found, for each sub-entry the switch replaces the tag in the packet with the outgoing tag, the link level information (e.g., MAC address) with the outgoing link level information and forwards the packet to the outgoing interface. The following are the important characteristics of the forwarding component:

- The forwarding decision is based on the *exact match* algorithm using a fixed length, short tag as an index. Therefore the forwarding procedure is simple and allows high forwarding performance (more packets per second). Additionally the simplicity of the forwarding component allows for its implementation in hardware.
- The forwarding decision is independent of the tag's granularity so the same forwarding paradigm can be used to support different routing functions. A good example demonstrating this is the way that the algorithm is used for unicast and multicast. In unicast, an entry in the TIB would only have a single [*outgoing tag, outgoing interface, outgoing link level information*] sub-entry. In multicast, an entry would have one or more sub-entries and the outgoing link information would include a *multicast MAC address*.

[1] In the case of multicast one incoming tag must be associated with many outgoing tags thus we have more than



Incoming Tag	Outgoing Tag	Outgoing Interface	Outgoing MAC address
$tag1_i$	tag1	port1	MAC1
$tag2_i$	tag2	port2	MAC2
$tag3_i$	tag3	port3	MAC3
	tag4	port4	MAC4
$tag4_i$	tag5	port5	MAC5
	tag6	port6	MAC6

Figure 5. Tag Information Base (TIB) format.

- The forwarding paradigm is independent of the routing functionality therefore any new routing functions can be readily.
- The tag-forwarding component is independent from the network layer (Layer-3) and it can be used with various Layer-3 protocols.

A decision has to be made by the designers of a tag-switching network regarding the tag encapsulation in a packet e.g., where to put the tag information. So far, the following possibilities have been proposed:

- A small tag header may be inserted between the Layer-2 and the Layer-3 headers.
- Encapsulation in the Layer-2 header.
- Encapsulation in the Layer-3 (network layer) header (e.g. using the Flow Label field in IPv6).

The flexibility of tag encapsulation allows the implementation of tag switching over a variety of different links, like point-to-point links, multi-access links, and ATM.

---

one sub-entries.

2. Control Component

In tag switching it is important to be able to identify Layer-3 routes by looking at a tag. This *binding* is essential. In different forwarding granularities a tag may support unicast (the tag identifies one route) or multicast (the tag identifies more than one routes). The control component is responsible for the creation of the tag-route bindings and for the distribution of the tag binding information among tag switches. The control component is modular with different modules supporting different routing functions. The benefit of this modular design is that when new routing functions emerge, tag switching will be able to support them by adding new modules.

Further details of how the control component is supposed to support the routing functions of *destination-based routing*, *hierarchy of routing knowledge*, *multicast* and *flexible routing* can be found in (Rekhter, 1997).

3. Tag Switching with ATM

Since both the tag switching forwarding paradigm and ATM cell forwarding is based on label swapping, tag switching technology can readily be applied to ATM switches by implementing the control component of tag switching.

The tag can be carried in the VCI field of the cell. If two levels of tagging are needed, then the VPI field could be used as well[1].

The switch should be able to participate as a peer in network layer routing protocols in order to be able to get the necessary control information for tag bindings. Routing protocols (e.g., OSPF for interior routing, BGP for exterior routing) are used for exchanging information about the network topology – both interior and exterior. This information must be stored in the switch so that it is able to successfully perform the bindings between tags and routes. Additionally, the switch may need to allocate more than one tag for the same route. This is required to avoid packet interleaving when packets arrive from different upstream tag switches that are destined for the same next hop.

---

[1] One level of tagging (the VCI field) is adequate for most applications

Therefore, the minimum requirements for an ATM switch to support tag switching are: capability to support network layer routing protocols and ability to implement the tag switching control component. An additional requirement may be support for some form of network layer forwarding.

The benefits of implementing tag switching on ATM switches are:

- It would greatly simplify the integration of ATM switches and routers because an ATM switch would appear as another router to an adjacent router. This fact could provide a more scalable alternative to the overlay model.
- It removes the necessity for ATM addressing, routing and signalling schemes since now the forwarding process is topology-driven and not flow based.
- It maintains the ATM switch's ability to support traditional ATM. The tag switching control component and the ATM control plane (the corresponding ATM control component e.g., PNNI[1]) would operate in a non-interactive manner[2].

4. Summary

The following characteristics of tag switching make it an interesting proposal:

- It is not constrained by a particular network layer protocol – it is a multiprotocol solution.
- The simplicity of the forwarding component facilitates high performance forwarding.
- The forwarding component can be implemented in high performance hardware such as ATM switches.

---

[1] Public/Private Network to Network Interface is the collection of signalling functions for setting up, maintaining, and closing a connection. Another such collection is the User to Network Interface (UNI) that refers to the signalling functions between a single workstation and the network.

[2] To achieve this we need to configure and partition appropriately the switch's resources so that each technology (tag switching and ATM) has enough resources available (like VPI/VCI space etc.).

- Tag switches have no impact on routers since they use the same routing protocols.
- The control component is flexible and may support a variety of forwarding functions (e.g., destination-based routing, multicast etc.).
- A tag can be associated with a wide range of forwarding granularities, which in turn allows for scalability and functionally rich routing.
- The combination of a wide range of forwarding granularities and the ability to evolve the control component independently of the forwarding component make tag switching a technology that enables graceful introduction of new routing functionality. This is very important in a rapidly evolving computer networking environment.

D. SUMMARY

In this chapter, we discussed computer networking issues that are of interest as a background for this thesis. We are interesting in particular in high-speed networks and IP over ATM technologies. We also discussed a novel routing technology, Tag Switching (Rekhter, 1997). In the next chapter, we will examine the problems that this technology introduces and we will present our protocol to address those problems.

IV. THE PROTOCOL

In this chapter, we examine the vulnerabilities introduced by the implementation of the forwarding component of tag switching. In particular, we describe how the security policy of an enclave can be violated by unauthorized access from inside the enclave to the outside world. We further propose a security protocol. The protocol can be applied as a module of the control component in a Network Access Controller (NAC) to minimize these vulnerabilities.

A. INSIDER ATTACKS

Tag switching – and more specifically the *label swapping* forwarding paradigm – introduces security vulnerabilities that have not been fully examined. For example (Rekhter, 1997) does not discuss any security issues.

In this section, we will try to identify a category of vulnerabilities related to the unauthorized use of network resources by an insider. We will examine how an enclave insider (with physical access to systems in the enclave), who has no authorization to send traffic outside the enclave, can exploit the label swapping forwarding paradigm to violate the access restriction imposed upon him/her. This, in turn, will violate the security policy of the enclave.

We focus attention on the forwarding component of tag switching. We do not try to examine the control component because it may differ greatly from implementation to implementation and it may evolve through time. On the other hand, the forwarding component – label swapping – is advertised to be a constant aspect of tag switching. Therefore, we are interested in making the forwarding component more secure.

In this context, we examine which of the attacks described in Chapter II, Section B, can be performed by an insider. We describe the principles on which possible attacks could be based rather than the exact techniques that can be used by an attacker. We believe that several case studies would be required to describe the latter, and they are beyond the scope of this thesis. Additionally, since it is virtually impossible to

exhaustively examine all the techniques that a resourceful attacker can come up with, we have decided to take a more generic approach.

Before looking at the possible attacks, we list our assumptions for the enclave:

- There are users in the enclave that do not have access privilege to the outside network and their packets are not allowed to leave the enclave. A situation like this may arise when the enclave enforces an access control mechanism as part of its security policy. The information security officer may decide to grant access privileges to a user and may decide to deny this privilege to another. For example, user Bob has been granted access privilege but user Alice has not. Therefore, Bob is authorized to send traffic out of the enclave but Alice is not authorized to do so and the packets that Alice is sending must be *denied access* to the external network.
- A link encryption scheme is not used (however an end to end scheme may be used). Therefore, the header of a packet goes in the open (but the contents of the packet maybe encrypted).
- The potential internal attacker has spoofing capabilities i.e., (s)he can read the header of any packet.

By examining the traffic in the network, the attacker can see the tags used in the packets sent out of the enclave by authorized users. He or she then can take two possible initial actions to compromise the security policy of the enclave:

- Steal and reuse a valid tag to send unauthorized traffic without notice.
- Alter tags to cause packets to be forwarded to the wrong destination without being detected.

Since the tag is the only routing information used by the forwarding component, a tag switch, upon receiving a packet with a known tag, would forward the packet without further checking[1].

[1] The tag switch looks up the Table Information Base (TIB) to find the incoming tag. Since the tag is valid, an

The remaining difficulty an attacker has to overcome is to ensure that the outgoing packets are going to be received by an intended partner in the outside. This can be achieved (comparatively simply) if the partner uses a sniffer program that picks up packets that leave the enclave. We will not examine how the attackers orchestrate this final stage of the attack. Our focus is how the internal attacker can manage to send packets out of the enclave. By denying this capability, we do not allow the attack to proceed to the final stage.

We consider the following three broad categories of insider attacks. We describe how each of them can be executed by an attacker when the label swapping forwarding paradigm is used in an enclave.

- *Disclosure*: Alice can steal a tag from Bob and start sending packets outside the enclave. This constitutes a direct violation of the DAC policy of the enclave. Additionally, another user authorized to access the network, could copy packets from the traffic sent by Bob, replace the tag with a new valid tag, and then resend them anywhere he or she wishes. Only end-to-end encryption would prevent the actual disclosure of data in the latter case[1].
- *Masquerade*: An unauthorized user can use a stolen tag to insert packets to the network. Additionally, higher layer computer communications protocols would not detect when the attacker steals and reuses the entire IP header. This kind of attack is also known as cut-and-paste attacks.
- *Timing modification*: An attacker can delay or replay packets – belonging to a legitimate user. For a replay of packets whose tags have expired in the switch's TIB, the attacker must steal a new, valid tag and use it for every packet intended to be replayed. The "faked" flow may not have to belong to the original source of the packets. In the case where the attacker needs to replay packets as a flow from a different host, then other parts of the header

---

entry exists. It simply replaces the incoming tag with an outgoing tag and adds a data link header to the packet. Then the packet is forwarded to the interface(s) designated in the sub-entry(s) of the incoming tag entry in the TIB.

[1] Covert channels are also a problem but they are beyond the context of this thesis.

have to be changed in order to "fool" the higher layers of the communications protocol.

B. THE PROTOCOL

1. Protocol Overview

In order to counter the kind of attacks described in the previous section, we propose the implementation of a protocol that will authenticate every packet that arrives at the tag switch. In this way only authorized packets i.e., packets that come from users with external access privilege, will be forwarded to the outside network. We also want the packet authentication and filtering scheme not to significantly affect the high-speed element of tag switching.

Our protocol requires authorized users to append a fixed-length *trailer* to every packet. This trailer will contain all the necessary information required for the authentication of the packet. The decision to use a trailer was motivated by the following two facts:

- We wanted to avoid parsing the variable-length IP header, which is computationally expensive.
- It is simple to extract a fixed number of bits from the end of a packet.

Our protocol will allow a firewall-like device, called Network Access Controller (NAC), to control the access from an enclave network to the outside. The NAC will play the role of a security "gateway" to the network. The NAC can be implemented at the first tag switch reached by packets on their way out of the enclave or may be a dedicated host at the edge of the enclave. A model for the protocol is shown in Figure 5. The implementation of the NAC will not affect or alter the tag switching technology. It will only add an intermediate authentication stage before the forwarding component of the first tag switch.

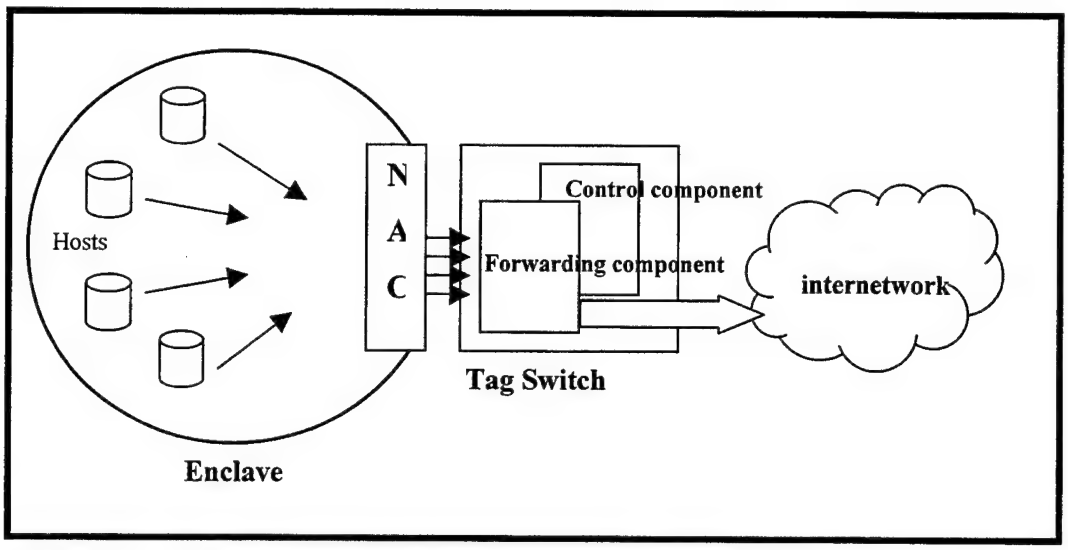


Figure 6. System Model for the Network Access Controller (NAC).

The protocol provides a session-based solution[1]. A session is a period of time that a *user-host* pair has access to the network through the NAC. A session terminates either when the host completes sending its traffic or when the NAC *times-out* the host, requesting reestablishment of the session. The time-out enhances security because it prevents an idle session from being hijacked. The reestablishment of a session does not necessarily mean interruption of the data transmission channel because session reestablishment can happen asynchronously, out-of-band. There will be, in the worst case, only a momentary decrease in throughput. A session may consist of several flows. For example, data flows, voice flows, and video flows may coexist during a single session.

The protocol uses the services of an Authentication Authority to authorize the access to the NAC (and subsequently access to the outside). The protocol also uses the services of a Key Distribution Authority that will provide a *session key* for each user session with the NAC. The Authentication Authority also provides a *ticket* to the user-host initializing this session. The ticket is used by the NAC to verify that the access is

[1] It has to be repeated when a session is established or reestablished. This will become clear in our later discussion of the various phases of the protocol.

legitimate. A detailed description of the verification process is presented in the next section. The NAC creates a *key-table* (an indexed table of keys) for the session. The table contains a sufficient number of keys for the entire duration of the session. A detailed description of the key-table is presented in the next section. A copy of the table is stored in the NAC and another copy is encrypted with the session key and then sent to the user-host. Only the intended user-host has the session key required to decrypt the table.

Before each packet leaves the host a fixed-length MAC for the packet is calculated and appended to the packet. Specifically, when the packet is formatted by the user-host, an appropriate key is chosen from the table (key-table). The key index of the selected key (index of the key in the key-table) denoted by *ki* is inserted into the second[1] word of the trailer (Figure 6). Then MAC is calculated using a one-way hash function on the composite message that consists of the original packet, the first two words of the trailer and the selected 32-bit key. We have made the MAC 128-bits long because we use MD-5 as the default one-way hash function, however, it is easy to change it to match the message digest size of other hash functions. Note that the key is used in the calculation of the MAC; however, it is not included in the packet that is sent. Only the original packet and the MAC trailer will be sent. The original packet payload can be encrypted before MAC computation if high degree of confidentiality is desired. The receiver will decrypt the payload after removing the trailer.

When receiving the packet, the NAC strips the original packet from the trailer and reads the key index (the second word of the trailer) and the MAC (the last 4 words). The next step for the NAC is to check if this is an authorized packet. The NAC looks up the key-table using the key index to find a key[2]. The key should be the same as the key used by the user-host for the MAC calculation. The obtained key is appended to the received packet and the MAC is recalculated at the NAC. If the calculated MAC is the same as the one received in the trailer then NAC knows the packet is authorized and will forward it.

---

[1] The first word is not used currently by the protocol but it is reserved for future use (version information etc.).

[2] If no key is found the packet will be chopped.

Otherwise the packet is unauthorized and the NAC rejects it. The packet is also rejected if the key is not found in the key-table.

2. List of assumptions

Our design of the NAC protocol is based on the following assumptions:

- The protocol is independent of the network layer technology that is going to be used. However, for simplicity we assume that Ipv6 is used.
- The protocol is independent of the link layer technology that is going to be used. However, we assume that tag switching is going to be implemented over ATM. This will allow us to view the tag as an indicator to the VCI that a flow is using. This notion of a tag is easy to understand and is practical.
- The key indexes in one key-table cannot have duplicates so that each key index corresponds to one and only one key. Therefore, we have a "limitation" of a total of 2^{32} key indexes or a total of 2^{32} keys in one table. While the large size appears to be overkill, the 32 bit-field allows for optimized indexing schemes. Following the VPI/VCI paradigm of ATM, we could use the first 16 bits to identify the flows or hosts (host ids) and the rest of them to identify the keys used for MAC calculation. We will not examine this optimized version, instead we will focus on the basic indexing scheme where all 32 bits are used as key indexes[1].
- An Authentication Server is available in the enclave. Any authentication server can be used for our protocol. We currently assume that the enclave uses the services of Kerberos 5. Kerberos 5 is very popular and already in use in many sites and will be included in Microsoft Windows NTv.5.
- A Key Distribution server is available within the enclave. We choose Kerberos 5 to play this role as well for the same reasons. Additionally,

[1] This scheme is very simple, however, we must keep in mind that it may create a very big aggregate key-table in the NAC (depending on the number of hosts with active flows in the enclave).

Kerberos 5 allows a choice of encryption algorithms (e.g., a client may ask for triple DES, or IDEA and Kerberos 5 will supply the corresponding session key).

- As we mentioned in the previous section the NAC may be the first tag switch or a firewall-like host playing the role of the security gateway[1]. In the latter case the NAC will simply filter and forward packets to the first tag switch. Without loss of generality we assume that the NAC is the first tag switch and that our protocol is going to be implemented on the NAC.

- The security overhead must be kept to a minimum. For this reason, we do not use link encryption for the packets because it is computationally costly. Instead, we have chosen to use a cheap, keyed one-way hash function to calculate the MAC for each packet. (The motivation for using this method of authentication was described in Chapter II.)

- The protocol can use any keyed one-way hash function to compute the MAC. We have selected keyed MD5 in order to demonstrate packet filtering can be done with a minimum security overhead. Our protocol overcomes the weakness of the MD5 algorithm – even the keyed version has been shown to be weak (Preneel, 1995) – with the use of *short lived* keys (e.g., the key has only a limited lifetime, denoted T_0, and it is "never" used again) and *periodic* key-table *refreshing* (we renew the key-table at regular intervals).

- The key-table exchange can be conducted out-of-band and, therefore, we assume that it does not add any significant overhead to the in-band data transmission.

- Periodically the NAC *times-out* a session, requesting a new authentication ticket from the user. This sequence of events can take place out-of-band. In

[1] The NAC does not necessarily introduce a single point of failure. In a distributed environment, we may have more than one NAC to implement our protocol. This will allow redundancy and load balancing in the enclave. The number of NACs an enclave needs is a network design decision.

fact, the user may not even notice that at all, except in the case when he will be prompted to enter a password.

- The user, after logging in at a host inside the enclave, is considered as a single entity, called the *user-host pair*. This is important because we are interested in being able to authenticate both the user and the machine. It is beyond the scope of this thesis to examine how this can be achieved.

3. Protocol Phases

We describe in detail *five* phases of our protocol. The description contains step-by-step actions that take place when the protocol is applied.

a. Initialization phase:

- The user logs in at a host inside the enclave
- The host requests authentication for the *user-host pair* from the Authentication Server (Kerberos 5)
- The user requests a *session key* from the Key Distribution Authority (Kerberos 5) in order to contact the Network Access Controller (NAC). In the request, the host specifies the conventional[1] encryption algorithm to be used (e.g., IDEA[2]).
- The Authentication Server authenticates the user-host and the Key Distribution Authority prepares a session key. A reply is sent back to the user-host pair that includes this *session key* and a *ticket*. The reply is encrypted with the algorithm of choice and with a secret key that is shared by the user and the Authentication Server. The ticket is a Kerberos ticket[3] that contains

[1] A public key algorithm can be used in the case that instead of Kerberos we chose to use X.509-based authentication (ChapterI.A.2).

[2] DES or triple-DES can also be used.

[3] We are interested only for these key components of the key and not the exact form of it. More details for Kerberos can be found in RFC 1510(Kohl, 1993).

the session key, the identity of the client (host), the lifetime of the key and a timestamp (for validity checking). The ticket is encrypted with the NAC's secret key. The host is going to send it to the NAC when it requests to initialize a session. The NAC uses the ticket to verify that the user-host is authorized by the Kerberos to access the outside network.

b. Connecting to the NAC

- The NAC receives the ticket from the host that wants to send traffic (packets).
- The NAC decrypts the ticket using its secret key (the one that is shared only with Kerberos)
- The timestamp and the lifetime of the ticket are checked so that the NAC can decide if the ticket is valid or not.
- If the ticket is not valid the NAC disregards the request (and may audit the attempt for security purposes).
- If the ticket is valid, the session key and the host id are extracted from the ticket by the NAC.

c. Key-table preparation and exchange

- NAC creates a key-table (we describe the format and functionality of the key-table in the next section) that will be shared by the host. In order to simplify the protocol description, we will assume that the host requested activation of a single flow, therefore, the key-table is going to be used for only one flow.
- The new key-table is stored into a database of keys that the NAC maintains for all hosts.
- A copy of the key-table is encrypted with the session key and is sent back to the host.

- The host decrypts the key-table; now both the host and the NAC share the same secret key-table.

d. Packet formatting at the host

- Every time a host wants to send a packet to the outside, it chooses a key from the key table. The process of choosing a key and related *rekeying* issues will be examined and described in detail in the next section. The *ki* is stored in the key index field (second word) of the trailer.
- The selected key is temporarily appended to the set (*packet, ki*) (first phase of the Secret Suffix Method).
- MD5 is applied to the whole (*packet, ki, key*) and a 128 bit MAC is obtained (second phase of the Secret Suffix Method).
- The created MAC is inserted into the last four words of the trailer (Figure 6).
- The composite message (*packet, trailer*) is then sent to the NAC.

e. Packet verification at the NAC:

- The message (*packet, trailer*) arrives at the NAC.
- The trailer is stripped from the packet, the *ki* is read, and the MAC is buffered.
- NAC looks up the aggregate table in order to retrieve the key that corresponds to the key index read from the trailer. (If the key index is not found the packet is rejected.)
- NAC repeats the Secret Suffix Method using the retrieved key and applying MD5 (repeating the same actions as the host) and creates a MAC.
- NAC compares the created MAC with the received MAC.
- If the MACs are not the same, the packet is rejected, otherwise, the packet is forwarded to the tag switching forwarding component.

It is clear from the above that our protocol is independent from tag switching, and therefore, can be applied to any *label swapping* forwarding architecture. Recall that we do not explore how routes are established in the tag switch because this is part of the control component functionality and beyond the scope of this thesis.

4. Protocol Components

In the following section, we describe the protocol components that were discussed in previous sections and we examine their functionality.

a. Packet Trailer

The packet trailer is a fixed length field appended to the end of each packet. The format of the trailer is shown in Figure 6. The length of the trailer is fixed, 196 bits (24 bytes). The first 32 bits (first word) allow extensibility (e.g., to allow storage of version number or other information) and are not currently used by our protocol. The second word (next 32 bits) is the *ki*. We see two straightforward ways for the use of the *ki*:

- The *ki* is used only for indexing keys in the key-table. This would require the NAC to be able to aggregate all the key-tables that are in use by different hosts in the enclave. Every time a packet arrives at the NAC the whole pool of keys (the aggregate table) must be searched in order to find the corresponding key. It is obvious that in this case the key indexes must be unique. The NAC must keep track of which have been assigned and which have been deallocated (not used any more). The later increases the complexity of the NAC, which is something that we try to avoid. Additionally, if the number of hosts is large, then we can expect the aggregate table to be large. Searching it may incur large delay in the authentication process.
- The *ki* also identifies the host that has created the packet. In this case the first part (e.g., first 16 bits) of the *ki* may play the role of a host identifier and the second part indexes the key in the table for that host. The NAC has to maintain a data structure, which will be a set of entries that will be indexed by

a host identifier. Each entry will be a key-table. In this way, there is no need to aggregate the allocated key-tables.

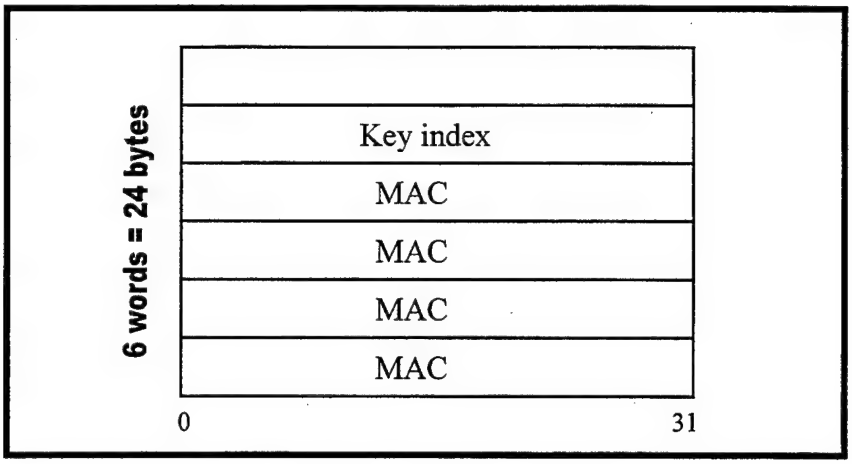

Figure 7. The packet *trailer*.

In this thesis, as we mentioned, we consider the former indexing scheme however, it is obvious that in both indexing schemes the authentication process is totally decoupled with the forwarding process (NAC is independent from tag switching).

b. Key-Table

The key-table is a container data structure that contains (*ki, key*) pairs. The number of entries (pairs) can be decided by the designer. As we mentioned, the table could be an aggregate table for all hosts or it could be an array of tables each of which is specific to a host, indexed by the host_id.

The keys must be randomly selected. The key indexes can be randomly selected too but it is not necessary. The key may be arbitrary long (given that the key-table allows dynamic memory allocation for the key storage). Key generation is not a trivial problem. However, any good random number generator could be used for generating keys.

Another parameter that has to be considered is the *lifetime of the key-table*. This is a design issue. The key-table should be refreshed more frequently if high security is desired. Refreshing the key-table may take place out-of-band, therefore, it does not

affect the data throughput for the current session. However there is the synchronization problem for the activation of the new table. The host and the NAC have to work together in order to have a seamless transition from the old key-table to the new. A three-way handshake – similar to the one used for establishing a connection in TCP – between the host and the NAC can be performed for this purpose.

5. Tag-key management

We had to address how the host could select a new key. We refer to it as the *rekeying problem*. Our initial approach was to make the choice of a key random (from the key-table) for each packet. The motivation was that we wanted the lifetime of a key to be the same as the lifetime of a packet and therefore, the lifetime of a packet (comparatively short) would be the time available to an attacker to break the message digest algorithm.

However, this would be true only if our key-table had at least as many entries as the number of packets that a host intends to send. Additionally, a mechanism would be needed to prevent the reuse of a key. In reality, since a key-table has limited length, then it would be impractical not to reuse keys. Key reuse increases the vulnerability to an attack.

Given the above premise (that we have to reuse keys more than once), we examined how long a key is exposed to an attacker with random key selections. In our analysis, we assumed the following:

- The lifetime of the key-table denoted T, is the same as the lifetime of the flow (e.g., the table remains the same throughout the transmission).
- The number of entries in the key-table is n.
- The flow for the current session consists of k packets.

It is obvious that if we use random key selections we allow the whole period T to the attacker to break the message digest algorithm. This happens because if a key is selected randomly a new packet may carry any of the key indexes (and subsequently any key) available in the table. Therefore, in this case the *time of vulnerability* is T.

Given that a key is selected for each packet, we deduced that *statistically* each *ki* is going to be used *k/n* times. This fact led us to the following observation. If we use the same key, repeatedly, *k/n* times (e.g., put the same *ki* in *k/n* packets) and then discard it we end up using each key index only for *T/n* time instead of T. We decide therefore to use a rekeying timer $T_0 = T/n$. It is obvious that this approach shrinks the time window that the attacker has available to break the message digest algorithm from *T* to *T/ n.* The selection of the next *ki* can be done sequentially[1] from the remaining *unused* key indexes in the table[2]. The only additional action is that every used key index must be marked as *unavailable* in the table or must be totally removed.

Practically, the calculation of *T/n* may not be feasible, so the designer may choose to use a fixed value of T_0 and whenever the key table is exhausted the key-table could be refreshed. The rekeying parameter T_0 is important to our protocol as it widens or narrows the window of vulnerability to the message digest algorithm.

[1] Since the key was produced by a random process, sequential selection of the next entry is acceptable.

[2] We can take advantage of this to optimize the lookup process of the key-table. The NAC could only look up the current and the next entries in the table and not the whole table for matching the key index.

V. PROTOCOL PERFORMANCE EVALUATION

Our protocol introduces delays when it is applied to a network. The major delay is caused by the message digest algorithm (MD5) that we use on every packet. This step is required to create MACs and authenticate packets based on them. Another delay is incurred by the comparison of the recomputed MAC and the received one. Other delays such as the table lookup for key retrieval are very small[1] compared to the MAC calculation and the MAC comparison.

Any message digest algorithm can be used for MAC generation. We have selected keyed MD5 because MD5 is popular, fast and easy to implement.

A. MD5 PERFORMANCE

Measuring the performance of MD5 is not a new problem. (Bosselaers, 1996) contains some results and a proposal for improving MD5's performance. According to (Bosselaers, 1996) the speed of MD5 (C code for x86 architectures) is 59.7 Mbits/sec on a 90 MHz Pentium. In order to improve the speed the authors rewrote the code in an assembly language and used the following optimizations[2]:

- Keep the code and data in the Pentium's on-chip caches.
- Organize the assembly code to take full advantage of the Pentium's two five-stage pipelines.

The above optimizations increased the throughput of MD5 to 113.7 Mbits/sec. The authors however, mention that "these figures refer to the performance of the hash function's basic building block: the compression function". If one wants to calculate the performance for hashing a message of arbitrary length, he/she has to take into account an additional iteration due to the padding block. (Bosselaers, 1996)

We perform our own measurements for two reasons:

---

[1] These operations can be optimized to minimize delay. We do not discuss the optimization details because they are beyond the scope of this thesis.

[2] More details on the optimizations can be found in (Bosselaers, 1996).

- To verify their results under a different environment without optimizations.
- To understand how different versions of MD5 are expected to perform.

We measured the throughput of an unoptimized version of MD5 implementation that has used the original MD5 code written in C by Ron Rivest (Rivest, 1992). We downloaded the source code from the Internet (ftp.funet.fi/pub/crypt/hash/mds/md5/). We compiled the code[1] using the Borland C++ 5.02 compiler. The measuring source code is included in Appendix E and the documentation of our[2] code is included in Appendix D. We measured the performance on two machines: a 133 MHz Pentium with 256 Kbytes of Level 1 cache and 48 Mbytes of RAM and a 200 MHz Pentium with 256 Kbytes of Level 1 cache and 48 Mbytes of RAM. During the experiment, we did not take any special measures to optimize the hardware and the software environment of the machines. The OS in the 133 Pentium was Microsoft Windows 95 and in the 200 Pentium was Windows NT 4.0. On both machines, the load was normal.

We applied MD5 to a series of messages of different sizes. The message sizes ranged from 512 bytes to 64 Kbytes. The results for Pentium 133 are shown in Figure 7 and the results for Pentium 200 appear in Figure 8. The measured throughput on the Pentium 133 machine was 35 Mbits/sec, regardless of the message size. On the Pentium 200 machine, the throughput was 60 Mbits/sec. Therefore, our results are in agreement with the performance of MD5 measured in (Bosselaers, 1996).

B. MAC COMPARISON

Another cause of overhead is the comparison of the received MAC taken from the trailer and the MAC that is recalculated by the NAC. Measurements of the comparison process showed that the overhead was negligible when compared to the one incurred by MD5. We tried two different comparison methods. The first method compares the 128-bit

[1] We had to clean the in order to be able to compile it with Borland C++ 5.02.

[2] We had to write a driver and a set of utility functions to interface with the MD5 code.

MAC byte by byte. The second method breaks the 128-bit MAC in four 4-byte words and casts each of them to integers. This results in two groups of four integers. We then subtract each integer from its corresponding peer. If all the (four) subtractions turn out to be *0* then the MACs have to be the same. The results of the two methods are shown in Figure 9 and Figure 10. The documentation and the code are included in Appendixes F and G respectively.

When we compared the two methods for performance, we noticed the following:

- If the MACs are the same, the for-loop that compares the MACs byte-by-byte has to be executed in full. In this case, our measurements show that the byte-by-byte method takes twice the time as the integer method.
- If the MACs are different then the two methods take approximately the same time.

Based on the results, we recommend the use of the integer method for MAC comparison. Note that the delay incurred by the MAC comparison is much smaller than the delay caused by the MD5 calculation; therefore, we can argue that both methods are acceptable.

VI. CONCLUSIONS AND FUTURE WORK

A. CONCLUSIONS

In this thesis we examined how the implementation of Tag Switching or other *label swapping,* packet-forwarding, fast-routing technologies increase the vulnerability of an enclave to *insider-attacks* (Chapter IV). This category of attacks is related to unauthorized access from inside an enclave to the outside network. We proposed a protocol to counter this category of attacks. We emphasize that we do not provide protection against *all* kinds of attacks.

The proposed protocol provides the means for fast packet authentication. The high speed is achieved by the following:

- Use of the *trailer*, which allows filtering at Layer 2.
- Use of a cheap and fast message digest algorithm (keyed MD5).
- We use key caching (the host has a table of keys) to allow fast rekeying.

To overcome the weaknesses of the keyed MD5 algorithm we use a limited key lifetime T_0 and periodic *rekeying*. Additionally, we use *key caching*, viz. we provide the host with a key-table, to allow fast rekeying[1]. The performance measurements indicated that it is possible to use our protocol in high-speed networks without unacceptable delays.

The protocol implements a Network Access Controller (NAC). The NAC can be regarded as an authentication module. It can be an intermediate stage between the enclave hosts and the forwarding module of a gateway. If a packet does not make it through the NAC, it will not reach the forwarding module. This can be useful to counter denial of service attacks. The modular nature of the NAC increases its flexibility since it can be easily combined with a variety of routing technologies and other security devices while totally independent of them. The only requirements for the NAC implementation are an

[1] Otherwise rekeying could incur unacceptable delays

Authentication Authority and a Key Distribution Authority, which are usually in place for a concerned network.

B. FUTURE WORK

A *formal verification* of the protocol is required. A prototype implementation in a distributed environment could follow. For the latter, we recommend the following phases:

- Modify the simulation code to use the services of a real Kerberos during the simulation. We recommend this to be done in a Windows NT environment.
- Make the code portable to UNIX machines. In the code, we used C++ Standard Template Library (STL) containers like *maps* and *vectors*. When we were writing the code, Sun's libraries for C++ were not totally compatible with STL. However, this may change in the near future. There are commercially available STLs for Sun machines.
- A Java implementation might be considered. Java has many attractive features that may benefit a prototype implementation of the protocol[1]. Java code is platform-independent, mobile and multi-thread enabled.
- Choose a communication mechanism like *sockets* to pass information back and forth between the different entities in the network, e.g., the host and the NAC. In an initial phase, communication could be simulated over IP. Our code simulates the communication channel using *files* for information exchange. Specifically, each entity (object) that wants to send a key-table creates a file and saves the key-table in the file. The receiving entity opens the file to retrieve the key-table.

[1] Slower performance must be expected with Java.

- Create daemons that will implement the NAC and will provide its services whenever a request arrives. The *nacclass* of our code can be used with little modification for this purpose.
- Simulate the Tag Switching *forwarding component* in software. This can be done if we have an ATM Network Interface Card (NIC) in the machine that implements the NAC. The packet after being authorized by the NAC could be forwarded to a preexisting VC to another machine that could acknowledge its receipt. This will simulate how a tag switch would behave over an ATM link. Knowledge of the ATM Application Programming Interface (API) will be required so that the NIC could be programmed to forward traffic to the preexisting VC.

Another issue that remains to be investigated is the trade-offs between various design parameters. Specifically, experiments can be conducted to evaluate the trade-offs between:

- The lifetime of a key T_0 and security.
- The lifetime of a key T_0 and the number of keys n.
- The key length and the lifetime of a key T_0.

APPENDIX A. DESIGN SPECIFICATION OF SIMULATION PROTOTYPE

1. Description

The simulation program models our protocol. The program will simulate what was described in Chapter IV of this thesis. The platform for the software will be a Pentium-based PC running Microsoft Windows NT 4.0 OS. The language for the simulation is C++ and the Borland C++ 5.02 compiler was used. The object model of the prototype is shown in Appendix B. Future work on this prototype may consist of the phases that were mentioned in Chapter VI.

The program will do the following:

- First it will create a host object, a Kerberos object and a NAC object
- The host object will be registered with Kerberos.
- The host object will request for a session key and a ticket from Kerberos.
- Kerberos will create them (the ticket will be deposited in KEY_TICKET_FILE so the host object will be able to retrieve it).
- The host object requests the start of a session with NAC. It sends the the name of the TICKET_FILE to the NAC. After the NAC verifies it it prepares a tableclass object (the key-table) and deposits it into the TABLE_FILE.
- The host retrieves the table from the TABLE_FILE and starts instantiating Ip_packetclass objects. The packets are formatted in accordance with our protocol using a key from the tablE. The message digest for the set (packet, trailer) is calculated using MD5. The data part of the packet object is retrieved from the contents on the MESSAGE_FILE (this file must pre-exist for the simulation to run; its name must be included in the constants.h file).
- The host requests authentication of each packet by the NAC, following the steps of the protocol. If the NAC authenticates the packet, the program displays that this packet was authenticated.

2. Layers

The file *constants.h* contains most of the system parameters that are used in the simulation. The filenames that are included are required for passing information between objects. The message that is going to be included as the packet content must be in a file, the name of this file must be assigned to MESSAGE_FILE in the constants.h. Without this file the simulation will not run.

The following classes were created (indentation indicates the hierarchy between the modules). We use the expressions host, Kerberos, NAC when we refer to the simulated modules.

Hostclass: models the functionality of a host.

Host_ticket_class: models the message that a host sends to NAC to establish a session. Prerequisite: the host has been authorized by Kerberos to do so and a valid ticket has been obtained.

Nacclass: models the functionality of a NAC.

Tableclass: models the functionality of a key-table.

Host_table_vector: models the database of tables that NAC must maintain.

Host_table_class: models each entry of the previous database.

Kerberosclass: models the functionality of a Kerberos module.

Host_key_vector: models the database that Kerberos maintains for hosts and their keys.

Host_key_class: models the entries of the previous database. Each entry contains the host_id and the secret key that the host shares with Kerberos.

Key_ticket_class: models the reply of Kerberos to a host that requests to communicate with NAC. It contains a session key and a ticket (intended for NAC).

ticketclass: models the ticket that Kerberos prepares. The ticket authorizes a host to further establish a session with NAC.

Ip_packetclass: models the functionality of an IP packet.

We also used the following *third party code*:

MD5: RSA Data Security, Inc. MD5 Message-Digest Algorithm (C code). We just cleaned up the code in order to compile and run it with Borland C++ 5.02 compiler.

Finally, we also wrote the following auxiliary code:

*Fileutil*s: provides services, needed by other modules, related to files and buffers.

Hashutils: Services used for interfacing the MD5 package functionality. We modified a demo driver program for MD5. This driver was originally written by Andy Brown (1994, asb@cs.hott.ac.uk). The code was included in the MD5 code that we downloaded from the Internet.

3. Modules

3.1 Hostclass

3.1.1 DESCRIPTION: the class simulates the functionality of a host inside an enclave that wants to get authorization for starting a session with NAC from a Kerberos server. The host needs to obtain a ticket and a session key, establish contact with NAC, obtain a key table and start sending ip_packets. The ip_packet will be formatted in accordance with the protocol we proposed in Chapter IV. We consider the user as part of the hostclass.

3.1.2 DATA:

host_id: an integer, that indicates the identity of the host. A real host id or an IP address could be used in more refined prototypes.

Host_key: a string that is the secret key that a host shares with Kerberos.

User_id: a string that identifies the user to Kerberos. The login name could be used.

ki_key_table: a tableclass object that will be used for getting ki_key pairs for packet formatting. In more refined prototypes a container object (an array or a vector) could be used to contain more than one tableclass objects according to the needs (how many

flows need to be active simultaneously) of the host.

Key_ticket_file: the name of the file that contains the session key and the ticket returned from Kerberos. We chose to read them from a file because it is easy to understand and implement. In a more refined implementation we could receive this information from a communication channel established between the host and Kerberos (e.g., a socket buffer or something similar). The simulated ticket is exposed, however this kind of ticket exchange is used only for this simulation.

Ticket_file: the name of the file containing the ticket that the host will send to NAC.

Session_key: this key is going to be used for the ki_key table exchange between the host and the NAC. In a more refined implementation the ki_key table needs to be encrypted with an encryption algorithm using this key.

3.1.3 FUNCTIONS:

Request_authentication

Input: kerberosclass & (a reference to a kerberos module)

Output: the data member key_ticket_file is defined.

Return value: boolean

Description: The host requests from Kerberos authentication by calling the kerberosclass' function that provides this service. Postcondition: the host has the name of the file that contains a session key and a ticket. If the authentication process fails then the return value is False.

Send_ticket

Input: none

Output: HOST_TICKET_FILE contains a host_ticket_class object.

Return value: char*

Description: The host creates a file containing the information that is necessary to NAC for host authentication. Postcondition: the

HOST_TICKET_FILE contains the host_id and a ticket (a host_ticket_class object). The name of this file is returned.

Get_table

Input: const char* TABLE_FILE_NAME

Output: the ki_key_table data member of the host is defined.

Return value: none

Description: The host opens the TABLE_FILE_NAME file and gets the ki_key_table that was prepared by NAC. The host now has a copy of the key table available.

Create_message

Input: char* message_file

Output: an ip_packetclass object is instantiated.

Return value: ip_packetclass

Description: creates and returns an ip_packetclass object. The ip_packetclass object is formatted by applying our protocol and using a ki_key pair chosen from the ki_key table. The *MESSAGE_FILE* name is included in the ip_packetclass object to simplify the process of reading the packet data. BE CAREFUL not to forget to create a message file and put its name in the constants.h file before starting the simulation. A new key is chosen every T_ZERO time.

Get_session_key

Input: none

Output: the date members session_key and ticket_file are defined.

Return value: none

Description: extracts the session key and the name of TICKET_FILE from key_ticket_class object that Kerberos created.

Postcondition: the data members session_key and ticket_file get values.

3.2 **Host_ticket_class**

3.2.1 DESCRIPTION: the class creates objects that contain the host_id and the name of the TICKET_FILE that contains the host's ticket. The objects are created by hosts. NAC uses them for host authorization.

3.2.2 DATA:

host_id: an integer, that identifies the host.

Ticket_file: a string, that is the name of the TICKET_FILE.

3.2.3 FUNCTIONS:

Host_id_is

Input: none

Output: none

Return value: int

Description: The host_id data member is returned.

Ticket_file_is

Input: none

Output: none

Return value: char*

Description: The ticket_file data member is returned.

3.3 **Nacclass**

3.3.1 DESCRIPTION: the class simulates the functionality of a Network Access Controller (NAC). NAC checks that a host (a user-host pair) requesting a session is authorized by Kerberos to do so. The NAC gets the ticket that Kerberos created when the host asked for authorization and extracts the ticket and the session key. NAC then creates a tableclass object (the ki_key table) for the session with the host. Stores the ki_key table in a database and sends a copy back to the host. In a more elaborate simulation, this copy must be encrypted with the session key. When the host starts sending ip_packets, the NAC must play its role in accordance with the protocol described in Chapter IV. Therefore, NAC "strips" the trailer from the ip_packetclass object, reads the ki and calculates the MAC for that ip_packet. If the

calculated MAC is the same with the one that was received in the packet trailer, then the packet is authenticated and can be forwarded.

3.3.2 DATA:

hosts_tables_db: the database of hosts and their tables. It is a host_table_vector object (a detailed description follows).

3.3.3 FUNCTIONS:

Prepare_table

Input: char*

Output: a tableclass object is instantiated and deposited in TABLE_FILE.

Return value: char*

Description: The name of the TICKET_FILE that contains the ticket of a host must be passed in as input. If the ticket is valid, NAC instantiates a tableclass ofbject and deposits it in the TABLE_FILE. The function returns the name of the TABLE_FILE. In the opposite case, the string "invalid_ticket" is returned. (Note: this can crash the program, if a function tries to open a file with name "invalid_ticket".)

Authenticate_packet

Input: ip_packetclass

Output: none

Return value: boolean

Description: an ip_packetclass object is passed in by value (a local copy of the object is created). The ki is read from the trailer and the MAC is calculated. If the calculated MAC is the same with the MAC that is stored in the ip_packetclass object trailer the function returns True, otherwise False.

3.4 **Tableclass**

3.4.1 DESCRIPTION: the class simulates the functionality of key table.The table is created by the Network Access Contoller (NAC) and is sent to a host. We chose to use the Standard Template Library *map* container for the key-table data

structure. The map contains (ki, key) pairs. The "first" (the index) of each pair is the ki and the "second" (the value) is the key. We chose the key to be an integer value created by the "srand ()" function of C++, as *seed* we use the host_id. This approach is suitable for demo only. In a more refined prototype, a more robust random number generator should be used. A key_generator could also be used. Additionally, keys could be chosen to be other than integers. The length of the class is defined by the constant NUM_PAIRS. The constant is defined in the constants.h file and we defined it to be 10. The kis are integers as well. We use integers in the range [1- NUM_PAIRS]. The kis could be chosen randomly without affecting the map implementation, but this is not necessary.

3.4.2 DATA:

ki_key_table: a map of NUM_PAIRS ki_key pairs (pairs of integers).

3.4.3 FUNCTIONS:

Get_next_ki

Input: none

Output: none

Return value: int

Description: the next ki in sequence in the key-table is chosen and returned to the caller.

Get_next_key

Input: int

Output: none

Return value: int

Description: a ki is passed in and the corresponding *key* is returned.

Initialize_the_key_pool

Input: int

Output: the tableclass is populated with NUM_PAIRS (ki, key) pairs.

Return value: none

Description: a host_id is passed in. This is used as seed and the values of the keys are randomly generated by the srand function. Postcondition: the ki_key table for that host is initialized.

Look_up_table_for_key

Input: int

Output: none

Return value: int

Description: a ki is passed in and the fuction looks up the map for the corresponding *key* that is returned.(Note: the program will crash if a non-existing tag is passed as an argument.)

3.5 **Host_table_vector**

3.5.1 DESCRIPTION: the class simulates the database of tables that is maintained by NAC. NAC uses this object to keep track of hosts and tables. We chose the Standard Template Library *vector* container to implement the database. The main reason was the flexibility of vectors (a detailed description follows). We can dynamically add more entries and remove old ones without caring for memory management. The vector elements are host_table_class objects (we explain their functionality in detail later). In this simulation, a host uses only one table. This can change easily in prototypes that are more refined, where a host can be associated with more than one table.

3.5.2 DATA:

Hosts_tables: the database, a vector of host_table_class objects.

3.5.3 FUNCTIONS:

Add_host_table

Input: a host_table_class object

Output: the database gets a new tableclass object.

Return value: none

Description: a copy or the host_table_class object is inserted in the vector.

Remove_host_table

Input: int

Output: a tableclass object is removed from the database.

Return value: none

Description: a host_id is passed in and the corresponding entry in the vector (the host_table_class object) is removed.

Is_host_authorized

Input: int

Output: none

Return value: boolean

Description: a host_id is passed in and the (vector) database is searched to find if an entry exists for this host. If a host_table_class object is found with the same host_id the function returns True, otherwise False.

Key_for_host_ki

Input: int, int

Output: none

Return value: int

Description: a host_id and a ki are passed in. The function first finds in the database the corresponding to the host table , and then fetches the key indexed by ki. This key is returned.(Note: the program will crash if no entry exists in the database for the host_id or if a non-existing ki is passed as a second argument.)

3.6 **Host_table_class**

3.6.1 DESCRIPTION: the class objects contain a host_id and a pointer to a tableclass object. Objects of this class are used as entries in the host_class_vector database maintained by NAC.

3.6.2 DATA:

Host_id: an integer that identifies the host.

Tableptr: a tableclass * pointing to the ki_key table that NAC created for the host.

3.6.3 FUNCTIONS:

Host_id_is

Input: non

Output: none

Return value: int

Description: returns the data member host_id, an int.

Table_is

Input: none

Output: none

Return value: tableclass *

Description: returns a *handle* (pointer) to the tableclass object pointed by the tableptr data member.

3.7 **Kerberosclass**

3.7.1 DESCRIPTION: the class simulates the Kerberos server. It has two databases, one for users (a user vector) and one for hosts and keys (host_key vector). A user or a host can register with Kerberos (enter the database) or can request authentication to begin a session with NAC. In the latter case, the Kerberos will look if the host or the user exist in its databases. If their user_id and the host_key entries are found, then a session key and a ticket are prepared. The session key in our case is stubbed to "sesskey". The ticket is a ticketclass object. The functionality of tickets has been simplified and we don't include timestamps (that real tickets have).

3.7.2 DATA:

Host_key_database: host_key_vector object, a database.

User_database: a vector of char* (user ids).

3.7.3 FUNCTIONS:

Register_host

Input: int, char*

Output: the host_key_database gets a new entry.

Return value: none

Description: an int (host_id) and a char* (key) is passed in and an entry is created in the Kerberos database. Postcondition: the host is now registered in Kerberos. Additionally,Kerberos has a commonly known key with the host.

Remove_host

Input: int

Output: an entry from the host_key_vector is removed.

Return value: none

Description: a host_id is passed in and the corresponding entry in the database is removed.

Register_user

Input: char*

Output: the user database gets a new entry.

Return value: none

Description: a char* user_id is passed in and an entry is created in the Kerberos user database. Postcondition: the user is now registered in Kerberos.

Remove_user

Input: char*

Output: an entry is removed from the user database.

Return value: none

Description: a user_id is passed in and the corresponding entry in the database is removed.

Request permission

Input: char*, int

Output: none

Return value: boolean

Description: a user (char*) at a host (int) are passed in and the vector database is searched to find them. If entries for both exist, then return True, otherwise False.

Send_key_ticket

Input: int

Output: the KEY_TICKET_FILE contains the session_key and the TICKET_FILE name.

Return value: const char*

Description: the KEY_TICKET_FILE is created. The file contains the session key and the name of the TICKET_FILE. The function returns the name of the file.

Create_session_key

Input: none

Output: none

Return value: char*

Description: returns the string "sesskey".

Create_ticket

Input: int, char*

Output: a ticketclass object is instantiated.

Return value: ticketclass

Description: a ticketclass object is instantiated and returned

3.8 **Host_key_vector**

3.8.1 DESCRIPTION: the class simulates the database of hosts and their corresponding keys that Kerberos maintains. Kerberos uses this object to keep track of the hosts and their keys. We chose the Standard Template Library *vector* container to implement the database. The vector elements are host_key_class objects (a detailed description follows). This simulates the database of secret keys that a real Kerberos server maintains.

3.8.2 DATA:

Hosts_keyes: the database, a vector of host_key_class objects.

3.8.3 FUNCTIONS:

Add_host

Input: int, char*

Output: a host_key_object is instantiated. The database host_key_vector gets a new entry.

Return value: none

Description: an int host_id and a char* (secret) key is passed in and the function creates a host_key_class object and adds it as an entry in the database. Postcondition: Kerberos has a secret key for this host.

Remove_host_key

Input: int

Output: an entry is removed from the host_key_vector (the database)

Return value: none

Description: a host_id is passed in and the corresponding entry in the vector (host_key_class object) is removed.

Is_host_registered

Input: int

Output: none

Return value: boolean

Description: a host_id is passed in and the database is searched to find if an entry exists for this host (subsequently, if a secret key is shared by Kerberos and the host). If a host_key_class object is found the function returns True, otherwise False.

3.9 **Host_key_class**

3.9.1 DESCRIPTION: the class objects contain an int host_id and a char* host_key. The host_key is supposed to be a secret key known only to the host and the Kerberos. Objects of this class are used as entries in the host_key_vector database maintained by Kerberos.

3.9.2 DATA:

Host_id: an integer that identifies the host.

Host_key: a char* that is the secret key known to Kerberos and the host.

3.9.3 FUNCTIONS:

Host_id_is

Input: none

Output: none

Return value: int

Description: returns the data member host_id, an int.

key_is

Input: none

Output: none

Return value: char *

Description: returns the data member host_key, a string

3.10 **Key_ticket_class**

3.10.1 DESCRIPTION: the class objects contain a session key and the name of the file that contains the ticket. Objects of this class are created by Kerberos and are sent to the host.

3.10.2 DATA:

Session_key: a char* (the string "sesskey")

Ticket_file: a char *(the filename).

3.10.3 FUNCTIONS:

Session_key_is

Input: none

Output: none

Return value: int

Description: returns the data member session_key, a string.

ticket_file_is

Input: none

Output: none

Return value: char *

Description: returns the data member ticket_file, a string.

3.11 **Ticketclass**

3.11.1 DESCRIPTION: the class objects contain a session key and a host_id (of the host that requested a session). Objects of this class are created by Kerberos and are sent to the host. The host in turn is going to send them to the NAC. (In a more refined prototype, real life Kerberos tickets can be used).

3.11.2 DATA:

Host_id : an int

Session_key: a char *(the string "sesskey").

3.11.3 FUNCTIONS:

Session_key_is

Input: none

Output: none

Return value: int

Description: returns the data member session_key, a string.

Host_id_is

Input: none

Output: none

Return value: int

Description: returns the data member host_id, an int.

3.12 **Ip_packetclass**

3.12.1 DESCRIPTION: the class objects simulate ip_packets. Objects of this class are created by hostclass objects and are sent to the NAC for authentication.

3.12.2 DATA:

Ki : an int, the key_index of the key that was used for MAC calculation for this

packet.

Host_id: an int that identifies the host.

filename: a char*, the name of the MESSAGE_FILE that contains the data that we want to send with this packet.

Mac: a unsigned char*, the message digest.

Note that the ki and the MAC consist the trailer of the packet.

3.12.3 FUNCTIONS:

mac_is

Input: none

Output: none

Return value: unsigned char*

Description: returns the data member mac, an unsighned char*.

ki_is

Input: none

Output: none

Return value: int

Description: returns the data member key_index, an int.

filename_is

Input: none

Output: none

Return value: char*

Description: returns the data member filename, a string. This file contains the data that we want to send with this packet.

host_is

Input: none

Output: none

Return value: int

Description: returns the data member host_id, an int. It is the id of the host that created this packet.

3.13 **Fileutils**

3.13.1 DESCRIPTION: the file contains auxilliary functions for copying files to files and copying files to string streams buffers.

3.13.2 DATA:none

3.13.3 FUNCTIONS:

filecopy

Input: char* fromfile

Output: char* tofile

Return value: none

Description: two filenames are passed in and the first file contents are copied and ovewrite the contents of the second file.

Copytobuffer

Input: char* fromfile, char* tobuffer, int key_index, int key

Output: none

Return value: char*

Description: a file name is passed in and its contents are dumped in the tobuffer string. Additionally the key_index and the key integers are appended to the string. This is protocol specific and a simulates the appending of a packet trailer.

3.14 **Hashutils**

3.14.1 DESCRIPTION: function that allow usage of the MD5 package are written here. The original code as it was mentioned before freely available in the Internet. The code is written in C and it was modified accordingly to accommodate the needs of our simulation.

3.14.2 DATA: n/a

3.14.3 FUNCTIONS:

MD5File

Input: char*

Output: none

Return value: unsigned char* (the 16 byte digest)

Description: a string, the name of a file that we want to calculate its contents MD5 is passed in. The message digest is calculated and returned

MD5String

Input: char*

Output: none

Return value: unsigned char*

Description: a string that we want to calculate its MD5 is passed in. The message digest is calculated and returned

MD5Print

Input: unsigned char*

Output: none

Return value: none

Description: the message digest is passed in, the function prints it as series of hex numbers.

MD5TestString

Input: char*

Output: none

Return value: none

Description: a string, that we want to calculate its MD5 is passed in. The message digest is calculated but it is not returned. This function is used only in the performance measurements of MD5.

compareDigest

Input: unsigned char*, unsigned char*

Output: none

Return value: boolean

Description: two message digests are passed in and are compared. The method of comparison here is byte by byte XORing. The function returns "true" if the message digests are the same. "False" otherwise.

Compare2Digest

Input: unsigned char*, unsigned char*

Output: none

Return value: boolean

Description: two message digests are passed in and are compared. The method of comparison here is the so called integer methode. We cast every four bytes of the 16 byte digest to integers and we subtract the corresponding ones. If all the results are 0 then the digests are the same. The function returns "true" if the message digests are the same. "False" otherwise.

// Date: 19 September 1998
// Description: the nacclass simulates the functionality of our firewall-like
//          network access controller and demos the protocol that we propose
//          Nac has the functionality to check if a host is authorized by
//          kerberos to send packets by examining the host's ticket. It then
//          creates a tableclass object (tag_key table), puts a copy in a
//          file encrypts it with the session_key that was retrieved from the
//          ticket and returns the filename of the (encrypted) file to the
//          host.Nacclass object puts the host_id and the tableclass object
//          in the hosts_tables_db database for further usage.
//          The nac authenticates the ip_packets that arrive.First a mac is
//          calculated for the message of the ip_packet. The mac is
//          calculated after the (ip_packet's) ki corresponding key is
//          appended to the message. By comparing the two macs (calculated
//          and the one contained in the ip_packet) the nac decides if the
//          ip_packet is authorized for forwarding.
//
// Assumptions: none
//

// Date: 19 September 1998
// Description:The table of (key_index,key) pairs created by nac and sent
//         to the host. The STL::map data structure was chosen to contain
//         the pairs of ki and key. The map"key" (first of the pair) is
//         the ki and the value (second of the pair) is the key. We chose
//         the key to be an integer value created by the srand function of
//         C++ with seed the host_id (for uniqueness of the random values).
//         This is a "naive" approach and was chosen for simplicity for demo
//         purposes. In a more serious implementation a key_generator must
//         be used and the key maybe chosen to be other than an integer
//         (a string maybe).
//           The class contains a map of NUM_PAIRS = 10 ki-key pairs and
//         the necessary functions to get the data. The auxilliary
//         functions are private so only the nac can get the data.
//           TO DO: CONSIDER USING RANDOM kis ALSO,DOES NOT AFFECT THE MAP,
//                NOT NECESSARY
//

APPENDIX D. DOCUMENTATION FOR MD5 PERFORMANCE TEST CODE

1. Description

The program measures the throughput of the MD5 message digest algorithm. The program uses the services of the "buffercreate.h" file. Main() creates a series of eight messages with sizes 512 bytes, 1, 2, 4, 8, 16, 32 and 64 Kbytes and applies MD5 on them. To calculate an average value for the throughput we calculate the MD5 of each of these messages 1000 times.

2. Layers

The main uses three function to measure the throughput:

Create_buffer: receives the ostrstream object (by reference) and a float that is the size of the message that we want to be created and it floods the object with the char "a" up to the size that was passed in as the second argument.

Calculate_time: receives an string (char*) and calculates how long it takes (in msecs) to apply MD5 on it 1000 times. It returns the calculated time.

calculate_throughput: the time that took to apply MD5 1000 times on a string and the size of the string and calculates the throughput. The result is in Mbits/sec

3. Modules

3.1 **main**

3.1.1 DESCRIPTION: The main() declares eight char*s and eight ostrstream output objects. The objects are declared without arguments therefore they dynamically allocate as many memory is required for the data that are going to be output to them. They stop allocating memory only when we "freeze" them using the .str() member function. Then the messages (buffers) are filled by calling the create_buffer( ) function and are frozen. For each of them we calculate the time that it takes for executing 1000 the MD5String() function and the throughput.

3.1.2 DATA: eight char*, eight ostrstreams

3.1.3 FUNCTIONS:

Calculate_time

Input: char*

Output: none

Return value: clock_t

Description: a string, is passed in and MD5 is applied 1000 on it. The time for all the itterations is calculated and returned. We try to calculate pure MD5 throughput thats why after we finish with MD5 we calculate the time that was spend as loop overhead and we subtract it (We itterate the loop 1000 times without doing anything)

Calculate_throughput

Input: clock_t, float

Output: none

Return value: float

Description: performs only the calculation of the throughput solving the equation.

3.2 **buffercreate**

3.2.1 DESCRIPTION: The file contains only one function that creates strings (buffers) of the requested size.

3.2.2. DATA: none

3.2.3. FUNCTIONS:

Create_buffer

Input: ostrstream &, float

Output: none

Return value: clock_t

Description: an ostrstream object is passed in by reference, and a float. The float is the size in Kbytes of the string that we want the object to contain at the end of the function execution. We output character "a" so

many times as the size parameter dictates in the ostrstream object. Then we convert it to a string and we return a reference to this string.

APPENDIX E. MD5 PERFORMANCE TEST CODE

//end throughputtest.cpp file
```

APPENDIX F. DOCUMENTATION FOR MAC COMPARISON PERFORMANCE TEST CODE

1. Description

The program measures the comparitive performance of the two MAC comparison functions.

2. Layers

The main uses four functions to calculate the performance:

Calculate_time_same: defines two same strings, applies MD5 on both and calculates how long it takes to execute a comparison of the two message digests one million times. It uses the byte XORing method (it is described in Appendix A).

Calculate2_time_same: defines two same strings, applies MD5 on both and calculates how long it takes to execute a comparison of the two message digests one million times. It uses the integer method (it is described in Appendix A).

Calculate_time_different: defines two different strings, applies MD5 on both and calculates how long it takes to execute a comparison of the two message digests one million times. It uses the byte XORing method (it is described in Appendix A).

Calculate2_time_different: defines two different strings, applies MD5 on both and calculates how long it takes to execute a comparison of the two message digests one million times. It uses the integer method (it is described in Appendix A).

4. Modules

3.1 **main**

3.1.1 DESCRIPTION: The main just makes the calls to the different functions that execute the comparisons and calculate the execution time and displays the resulst to the user explaining what it does.

3.1.4 DATA: four type clock_t variables (to accommodate the results of the functions)

3.1.5 FUNCTIONS:

Calculate_time_same

Input: none

Output: none

Return value: clock_t

Description: the function declares and defines two *same* strings and calculates their message digests. The 16 byte digests are compared using the byte XORing method (byte by byte XOR ing). The comparison is repeated 1000000 times for averaging the result. The time is calculated and returned.

Calculate2_time_same

Input: none

Output: none

Return value: clock_t

Description: the function declares and defines two *same* strings and calculates their message digests. The 16 byte digests are compared using the integer method (cast to four integers and subtract). The comparison is repeated 1000000 times for averaging the result. The time is calculated and returned.

Calculate_time_different

Input: none

Output: none

Return value: clock_t

Description: the function declares and defines two *different* strings and calculates their message digests. The 16 byte digests are compared using the byte XORing method. The comparison is repeated 1000000 times for averaging the result. The time is calculated and returned.

Calculate2_time_different

Input: none

Output: none

Return value: clock_t

Description: the function declares and defines two *different* strings and calculates their message digests. The 16 byte digests are compared using the integer method. The comparison is repeated 1000000 times for avereging the result. The time is calculated and returned.

APPENDIX G. MAC COMPARISON PERFORMANCE CODE

```
//*****************************************************************************
//*****************************************************************************
// File : MAComparetest.cpp
// Name : Ioannis Kondoulis
//
// Operating Enviroment: Windows NT 4.0
// compiler: Borland C++ for Windows, ver. 5.02
// Date: 17 Sep 1998
// Description: This is a test program that measures the performance of the two
//          functions that compare 128 bit MACs.The functions themselves are
//          included in the file hashutils.c that interfaces the MD5 code.
//          It uses the clock_t for the measurement of time. Because the time
//          for the comparison is very small we execute it one million times
//          in order to measure it. The result we get is in [msec].
// Assumptions:none
//
// Warnings: none
//
//*****************************************************************************
//
#include <string.h>
